And now.

**Sepharose
CL**

**Gel filtration and *RP383*
Affinity chromatography even
in 6M GuHCl, organic solvents, 8M urea,
3M KSCN
at pH3, pH12, 80°C**

CROSS-LINKED SEPHAROSE is a new beaded agarose chromatographic medium with exceptional stability and extremely low non-specific adsorption. It can be used with confidence in the most extreme dissociating media including strong solutions of urea, guanidine hydrochloride and chaotropic salts. Sepharose CL can also be used in organic solvents.

You can sterilize Sepharose CL repeatedly by autoclaving at 110°C - 120°C. Cross-linked Sepharose is available in three types: Sepharose® CL-2B, CL-4B and CL-6B.

Ask for the free booklet with data and details of new techniques, from your supplier of Sephadex®, Sepharose® and other separation media.

Guide to authors

● Articles are up to 3,000 words in length with at most six displayed items (figures and tables) and may either be reports of major research developments in a subject or broader reviews of progress.

● Letters are brief reports of research of unusual and wide interest, not in general longer than 1,000 words; at most they have three or four displayed items (figures and tables).

● 'Matters Arising' permits occasional short discussion of papers that have previously appeared in *Nature*. There is a limit of 300 words.

Manuscripts may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the *Système International*. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible, *exp (a)* is preferred to *e^a* if 'a' is more than one character. Articles should be accompanied by an abstract of not more than fifty words listing the main conclusions.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) To refer to several references by the same author at once, only one reference number need be given.

(ii) Cite first and last pages.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed. (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished work' should be incorporated in the text.

Artwork should be sent with the manuscript. All artwork should be marked with the author's name. Line drawings should preferably be in Indian ink on heavy cartridge paper, although other materials are acceptable; thin, shiny, folded, torn or heavily handled material should be avoided. Matt rather than glossy photographs are preferred. Figures are usually reduced to one column width. The originals should be about as wide as a page of *Nature*. Figures, particularly maps, should contain nothing but essential material. It is preferred that the original be unlabelled, but with a copy containing lettering. Labelling on photographs should if possible be avoided entirely. We are always glad to see artwork for possible use on the cover, whether or not it is associated with a manuscript, but cannot guarantee the return of material.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

A fuller guide appeared in *Nature* (246, 238; 1973).

Prolactin levels and duration of *postpartum* anoestrus in lactating ewes—

G. Kann and J. Martinet

63

Structure of DNA molecules in yeast meiosis—G. Simchen and A. Friedmann

technique—M. S. Roberts, E. J. Triggs and R. A. Anderson 225

Macrophages on intrauterine contraceptive devices produce prostaglandins—
L. Myatt, M. A. Bray, D. Gordon and J. Morley 227

Cytocidal and cytostatic effects of activated peritoneal leukocytes—O. A. Holtermann,
B. A. Lisafeld, E. Klein and J. Klostergaard 228

Partial characterisation of Ia antigens on murine thymocytes—J. W. Goding, E. White
and J. J. Marchalonis 230

Isolation and properties of a murine spleen cell Fc receptor—L. Rask, L. Klareskog,
L. Östberg and P. A. Peterson 231

Tumour rejection properties of solubilised TSTA from an SV40-induced neoplasm—
L. W. Law, O. Hemtksen and E. Appella 234

Possible role for H-Y antigen in the primary determination of sex—S. S. Wachtel, S. Ohno,
G. C. Koo and E. A. Boyse 235

Expression of H-Y (male) antigen in phenotypically female *Tfm/Y* mice—D. Bennett,
E. A. Boyse, M. F. Lyon, B. J. Mathieson, M. Scheid and K. Yanagisawa 236

Effect of morphine on a depolarising dopamine response—P. R. Myers, D. R. Livengood
and W. Shan 238

Receptor potential and impulse initiation in two varieties of reptilian muscle spindle—
Y. Fukami 240

Binding of aldosterone by mitochondria-rich cells of the toad urinary bladder—
V. S. Sapirstein and W. N. Scott 241

Cytochalasin B increases collagenase production by cells *in vitro*—E. D. Harris, Jr.,
J. J. Reynolds and Z. Werb 243

Guide to authors

● Articles are up to 3,000 words in length with at most six displayed items (figures and tables) and may either be reports of major research developments in a subject or broader reviews of progress.

● Letters are brief reports of research of unusual and wide interest, not in general longer than 1,000 words; at most they have three or four displayed items (figures and tables).

● 'Matters Arising' permits occasional short discussion of papers that have previously appeared in *Nature*. There is a limit of 300 words.

Manuscripts may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the *Système International*. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible, $\exp(a)$ is preferred to e^a if 'a' is more than one character. Articles should be accompanied by an abstract of not more than fifty words listing the main conclusions.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) To refer to several references by the same author at once, only one reference number need be given.

(ii) Cite first and last pages.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed. (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished work' should be incorporated in the text.

Artwork should be sent with the manuscript. All artwork should be marked with the author's name. Line drawings should preferably be in Indian ink on heavy cartridge paper, although other materials are acceptable; thin, shiny, folded, torn or heavily handled material should be avoided. Matt rather than glossy photographs are preferred. Figures are usually reduced to one column width. The originals should be about as wide as a page of *Nature*. Figures, particularly maps, should contain nothing but essential material. It is preferred that the original be unlabelled, but with a copy containing lettering. Labelling on photographs should if possible be avoided entirely. We are always glad to see artwork for possible use on the cover, whether or not it is associated with a manuscript, but cannot guarantee the return of material.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

A fuller guide appeared in *Nature* (246, 238; 1973).

Induction of synthesis of bacterial protein by excretory product of the alga <i>Chlamydomonas reinhardtii</i> y-1—W. J. Stegeman and J. K. Hooper	244
Kinetics of inactivation of histone mRNA in the cytoplasm after inhibition of DNA replication in synchronised HeLa cells—D. Gallwitz	247
<i>In vitro</i> transcription of a late class of phage SP01 genes—J. Pero, R. Tjian, J. Nelson and R. Losick	248
N ⁶ , O ^{2'} -dimethyladenosine a novel methylated ribonucleoside next to the 5' terminal of animal cell and virus mRNAs—C.-M. Wei, A. Gershowitz and B. Moss	251
Two distinct mechanisms of synthesis of DNA fragments on colicin E1 plasmid DNA—J.-I. Tomizawa	253

Matters arising

Empirical formulae for Student's function—V. A. Moss	255
Cape diastrophism—J. F. Truswell	255
Reply—J. H. de Beer, J. S. V. van Zijl and F. K. Bahnemann	255
Chocolate, β -phenethylamine and migraine re-examined—J. W. Schweitzer, A. J. Friedhoff and R. Schwartz	256

BOOK REVIEWS

Introduction to Geology. Volume 2: Earth History (H. H. Read and Janet Watson)—Kingsley Dunham	257
Peptide Transport in Protein Nutrition (D. M. Matthews and J. W. Payne, editors)—Dennis Parsons	257
Guide to the Marine Stations of the North Atlantic and European Waters. Part 1: Northern Europe and the East Atlantic Coast (J. E. Webb, compiler)—J. E. Smith	258
Comprehensive Virology (Heinz Fraenkel-Conrat and Robert E. Wagner, editors)—J. S. Porterfield	258

ARTICLES

Letters from Einstein to de Sitter on the nature of the Universe—C. Kahn and F. Kahn	451
An accelerating Universe—J. E. Gunn and B. M. Tinsley	454
Identification of two copies of the gene for the elongation factor EF-Tu in <i>E. coli</i> —S. R. Jaskunas, L. Lindahl, M. Nomura and R. R. Burgess	458

LETTERS TO NATURE

New radio map of Cassiopeia A at 5 GHz—A. R. Bell, S. F. Gull and S. Kenderdine	463
Observations at 6 cm of the solar active region—M. R. Kundu and C. E. Alissandrakis	465
Special relativity and very long baseline interferometers—D. S. Robertson	467
Mode of propagation of penumbral waves—P. Malby	468
Basal complex of Fuerteventura (Canary Islands) is an oceanic intrusive complex with rift-system affinities—C. J. Stillman, J. M. Fuster, M. J. Bennell-Baker, M. Muñoz, J. D. Smewing and J. Sagredo	469
Magnetic results from basalts and sediments from the Nazca Plate—H. P. Johnson and J. M. Ade-Hall	471
Evidence for a new aluminium phosphate phase from reaction rate of phosphate with aluminium hydroxide—W. H. van Riemsdijk, F. A. Weststrate and G. H. Bolt	473
Excess of atmospheric neon in pumice from the Islands of Lipari—P. Bochsler and E. Mazor	474
Long range transport of toxaphene insecticide in the atmosphere of the western North Atlantic—T. F. Bidleman and C. E. Olney	475
New interglacial site at Sugworth—D. J. Briggs, D. D. Gilbertson, A. S. Goudie, P. J. Osborne, H. A. Osmaston, M. E. Pettitt, F. W. Shotton and A. J. Stuart	477
Adverse effects of maternal alcohol consumption on pregnancy and foetal growth in rats—W. J. Tze and M. Lee	479
Alcohol prolongs time course of glare recovery—A. J. Adams and B. Brown	481
Macrophage proliferation induced <i>in vitro</i> by a lymphocyte factor—J. W. Hadden, J. R. Sadlik and E. M. Hadden	483
DNA present in multilayer rosette formed by lymphocytes stimulated with phytohaemagglutinin—G. Politis, M. G. Plassara and H. Thomou-Politi	485
Are contact hypersensitivity cells cytotoxic?—G. Dennert and L. E. Hatlen	486
Appearance of foetal antigens in somatic cells after interaction with heterologous sperm—P. J. Higgins, E. Borenfreund and A. Bendich	488
Sulphide-dependent anoxygenic photosynthesis in the cyanobacterium <i>Oscillatoria limnetica</i> —Y. Cohen, B. B. Jørgensen, E. Padan and M. Shilo	489
Light inhibits the labelling of gangliosides in chicken retina—B. L. Caputto, A. H. R. Maccioni and R. Caputto	492
Influence of antidiuretic hormone on release of lysosomal hydrolase at mucosal surface of epithelial cells from urinary bladder—R. J. Pietras, B. J. Seeler and C. M. Szego	493
Action of various antidepressant treatments reduces reactivity of noradrenergic cyclic AMP-generating system in limbic forebrain—J. Vetulani and F. Sulser	495
Tubulin in postsynaptic junctional lattice—B. B. Walters and A. I. Matus	496
Post-transcription control of isocitrate lyase induction in the eukaryotic alga <i>Chlorella fusca</i> —A. H. Scragg, P. C. L. John and C. F. Thurston	498
Is Fanconi's anaemia defective in a process essential to the repair of DNA cross links?—M. S. Sasaki	501

Singular Optimal Control Problems

David J. Bell and David H. Jacobson

October/November 1975, xii+190 pp., £5.80/\$15.00 0.12.378750.5

The purpose of this book is to collect together all known results in optimal control theory (as well as appropriate computational methods) which can be applied to the singular problems in optimal control and which up to now have been scattered in numerous journals. Complete and self-contained, the volume begins with an historical survey of singular control problems and leads to the presentation of important, recent results in the field. There are specific real-world applications and the authors discuss those avenues of research which require further investigation.

Studies in Archaeological Science

Soil Science and Archaeology

Susan Limbrey

October/November 1975, xvi+342 pp., £8.40/\$21.75 0.12.785477.0

This book, both a work of reference and a field manual, clarifies the relationship between people whose remains are the subject of archaeological study and the soils upon which those people depended for food and resources. Dr. Limbrey gives an account of soil processes, which have an important effect on the distribution and condition of material remains, the formation of soil profiles and the consistency of soils. She then considers the distribution of soil types in terms of the environment under which they have formed and the history of their development under changing conditions. Those British soils strongly influenced by man's activities in disturbing, clearing and cultivating the land are described in detail, as are soils of other regions. The final section deals with soils in relation to the work of field archaeologists.

Computer Science and Applied Mathematics: A series of mono graphs and textbooks

Graph Theory An Algorithmic Approach

Nicos Christofides

October/November 1975, xvi+400 pp., £12.50/\$32.25 0.12.174350.0

This book deals with the algorithmic and computational aspects of graph theory, to the virtual exclusion of pure theory. The author's primary aim is to acquaint his audience with the main techniques for the solution of important graph theory problems, to develop new algorithms and to unify and relate these methods into a coherent body of knowledge. Intended for those working in operations research, computer science and civil, transport and electrical engineering, the book will leave the reader in a position to relate and adapt the basic concepts to their own fields of application, and derive new ways of solving their own problems.

Leucocytes: Separation, Collection and Transfusion

Proceedings of the International Symposium on Leucocyte Separation and Transfusion held at the Royal Postgraduate Medical School, London in 1974

edited by J. H. Goldman and R. M. Lowenthal

October/November 1975, xxxvi+602 pp., £13.80/\$35.75 0.12.288550.3

The separation and collection of leucocytes from appropriate donors and their transfusion to patients with malignant disease or aplastic anaemia is a rapidly developing aspect of supportive care. This book contains the proceedings of an International Symposium convened in recognition of the recent advances in the technology required both to separate leucocytes from the peripheral blood and use collected granulocytes in the treatment of infection in leucopenic patients. Other uses of continuous blood flow blood cell separators were also considered: these include collection of acute leukaemia cells, treatment of chronic leukaemia and plasmapheresis.

The Role of Fats

edited by A. J. Vergroesen

October/November 1975, xiv+494 pp., £14.00/\$36.25 0.12.718050.8

Dr. Vergroesen and his colleagues discuss the pathological effects of fats in relation to diabetes, atherosclerosis, arterial thrombosis and obesity, analysing the process of fat absorption and the role of different fatty acids. They consider the possibilities of preventing any harmful effects produced by certain fats, particularly rapeseed oil which is used extensively for domestic consumption. The book includes a lengthy discussion on the importance of vitamin E in its capacity as a natural antioxidant. It is claimed that an increase in consumption of polyunsaturated fatty acids will lower the tendency of blood platelets to adhesion and aggregation, so decreasing the risk of arterial thrombus formation.

Guide to authors

● Articles are up to 3,000 words in length with at most six displayed items (figures and tables) and may either be reports of major research developments in a subject or broader reviews of progress.

● Letters are brief reports of research of unusual and wide interest, not in general longer than 1,000 words; at most they have three or four displayed items (figures and tables).

● 'Matters Arising' permits occasional short discussion of papers that have previously appeared in *Nature*. There is a limit of 300 words.

Manuscripts may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the *Système International*. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible, $\exp(a)$ is preferred to e^a if 'a' is more than one character. Articles should be accompanied by an abstract of not more than fifty words listing the main conclusions.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) To refer to several references by the same author at once, only one reference number need be given.

(ii) Cite first and last pages.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed. (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished work' should be incorporated in the text.

Artwork should be sent with the manuscript. All artwork should be marked with the author's name. Line drawings should preferably be in Indian ink on heavy cartridge paper, although other materials are acceptable; thin, shiny, folded, torn or heavily handled material should be avoided. Matt rather than glossy photographs are preferred. Figures are usually reduced to one column width. The originals should be about as wide as a page of *Nature*. Figures, particularly maps, should contain nothing but essential material. It is preferred that the original be unlabelled, but with a copy containing lettering. Labelling on photographs should if possible be avoided entirely. We are always glad to see artwork for possible use on the cover, whether or not it is associated with a manuscript, but cannot guarantee the return of material.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

A fuller guide appeared in *Nature* (246, 238; 1973).

Organisation and evolution of <i>Drosophila virilis</i> heterochromatin—G. Holmquist	503
Segregation of RD-114 and FeLV-related sequences in crosses between domestic cat and leopard cat—R. E. Benveniste and G. J. Todaro	506
Identification of heat-dissociable RNA complexes in two porcine coronaviruses—D. J. Garwes, D. H. Pocock and T. M. Wijaszka	508
Presence of factor VIII-related antigen in blood platelets of patients with Von Willebrand's disease—B. N. Bouma, J. M. Hordijk-Hos, S. de Graaf, J. J. Sixma and J. A. van Mourik	510

Announcing... Technicon Research Grants for Biomedical and Industrial Instrumentation

Technicon Instruments Corporation announces its second annual competition for grants in support of research in biomedical and industrial instrumentation. Initiated last year in North America, the program is now being expanded to include researchers in Western European and Mediterranean nations.

PURPOSE

To identify and support research on novel concepts or technologies in biomedical and industrial instrumentation with a view toward commercial application of the results of the research.

AWARDS

Meritorious proposals will be considered for grants covering direct and indirect costs for one year, to a maximum of \$100,000 for each grant. In most cases grantees will be eligible for renewal of their grants for a second year, and in exceptional circumstances support for a third year may be considered.

ELIGIBILITY

Open to faculty members and scientists from colleges, universities, medical centers, and nonprofit research institutes.

SCOPE

Basic and applied research proposals will be considered, including those for a new concept or support for development of a process or device. Each submission will be judged for scientific merit as well as for its potential for practical utilization.

The following examples are illustrative, and do not represent the limits of suitable proposals:

In the biomedical and diagnostic area:

New and improved diagnostic procedures of broad utility adaptable to automation for the determination of the chemical constituents of body fluids (e.g., blood and urine), for measurement of enzyme activities, for the differentiation of cells and viruses, and for other common and important medical laboratory tests.

New methods of imaging or diagnosing internal organs via x-rays, ultrasonics, or other non-invasive techniques.

Instruments for the detection and diagnosis of dental pathology.

In the industrial area:

Automated instrumentation and methods for the analysis and characterization of a wide

variety of materials, including agricultural products, drug preparations, minerals, and other industrial products.

Instrumentation for industrial process control, for pollution analysis and control, and novel procedures for the analysis of food products.

INVENTIONS AND PATENTS

Ownership of inventions will be determined by the policies of the institutions. However, Technicon will be granted an option to acquire an exclusive license to inventions, the terms of which will be negotiated at the time of the grant award.

EVALUATION

Proposals will be reviewed by distinguished academic scientists outside of Technicon. Those proposals recommended by these reviewers will then be evaluated with respect to their importance to the medical and industrial communities served by Technicon.

DEADLINE

Final proposals must be submitted by December 15, 1975.

FURTHER INFORMATION

Interested investigators are advised to obtain full details, including a short-form "preproposal" application prior to submission.

In North America, write Technicon Research Grant Program, c/o Dr. Morris H. Shamos, Technicon Instruments Corporation, Tarrytown, New York 10591.

In Western Europe and the Mediterranean area, write Technicon Research Grants Program, c/o Dr. Harry W. Holy, Technicon International Division S.A., 12-14 Chemin Rieu, 1208 Geneva, Switzerland.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

A fuller guide appeared in *Nature* (246, 238; 1973).

Modulation of macrophage Fc receptor expression <i>in vitro</i> by insulin and cyclic nucleotides—J. Rhodes	597
Molecular differences of exposed surface proteins on thrombasthenic platelet plasma membranes—D. R. Phillips, C. S. P. Jenkins, E. F. Lüscher and M.-J. Larrieu	599
Actin-tubulin homology revisited—H. A. Alicea and F. L. Renaud	601
Cross innervation and the regulatory protein synthesis of rabbit soleus muscle—G. W. Amphlett, S. V. Perry, H. Syska, M. D. Brown and G. Vrbova	602
New peptide in the vertebrate CNS reacting with antigastrin antibodies—J. J. Vanderhaeghen, J. C. Signeau and W. Gepts	604
Role of sodium in neuronal uptake of monoamines and amino acid precursors—J. Bruinvels	606
Enteropancreatic circulation of digestive enzyme as a conservation mechanism—H. Götze and S. S. Rothman	607
Increased breakdown of glycosaminoglycans and appearance of corrective enzyme after skin transplants in Hunter syndrome—M. F. Dean, H. Muir, P. F. Benson, L. R. Button, J. R. Batchelor and M. Bewick	609
Human serum lyses RNA tumour viruses—R. M. Welsh, Jr, N. R. Cooper, F. C. Jensen and M. B. A. Oldstone	612
Presence of antibody to a primate RNA virus in human plasma—B. S. Kim	614
Discrimination between eukaryotic and prokaryotic, and formylated and non-formylated, initiator tRNAs by eukaryotic initiation factor EIF-3—R. S. Ranu and I. G. Wool	616
Blocked, methylated 5'-terminal sequence in avian sarcoma virus RNA—Y. Furuichi, A. J. Shatkin, E. Stavnezer and J. M. Bishop	618
Thermodynamic activation parameters of fish myofibrillar ATPase enzyme and evolutionary adaptations to temperature—I. A. Johnston and G. Goldspink	620
C ₄ photosynthesis in plants from cool temperate regions, with particular reference to <i>Spartina townsendii</i> —S. P. Long, L. D. Incoll and H. D. Woolhouse	622
X-ray evidence of temperature-dependent conformational disorder of hydrogen-bonded carboxylic acid molecules in crystal structures—J. A. Kanters, G. Roelofsens and J. Kroon	625
Errata	626
Corrigendum	626
BOOK REVIEWS	
The Representation of Meaning in Memory (Walter Kintsch)—P. N. Johnson-Laird	627
Honey: A Comprehensive Survey (Eva Crane, editor)—Paul Wix	627
The Filament Fungi. Volume 1: Industrial Mycology (J. E. Smith and D. R. Berry, editors)—J. Colhoun	628
Mycogenetics: An Introduction to the General Genetics of Fungi (J. H. Burnett)—L. C. Frost	628
Computer Chess (Monroe Newborn)—Nigel J. Holloway	629
Mathematics and Computers in Archaeology (J. E. Doran and F. R. Hodson)—M. L. Shackley	629
Synapses and Synaptosomes: Morphological Aspects (D. G. Jones)—H. F. Bradford	630
The Chordates (R. McNeill Alexander)—Barry Cox	630
Reader enquiry service	xx

Nature in Europe

UNTIL the beginning of 1975, European readers could only get *Nature* by surface mail, with delays of up to three weeks. During 1975, we have used air-speeded delivery for all European subscriptions. This has cut the delay to a few days. Postal rates applicable at the beginning of 1975 allowed us to do this for only £1.50 above the UK price.

Substantial increases in postal charges now make it impossible to keep the surcharge that low so, on renewal, European subscribers will be able to choose to pay either £35 (the same as the UK price) for a surface-mail subscription or £40 for an air-speeded subscription.

ARTICLES

Simulating experiments for Spacelab— <i>B. Carl, D. H. Martin, E. Puplett and J. E. Harries. A. W. Peterson and A. W. Kieffaber. L. J. Caroff. J. Crawford, P. Rothwell and N. Wells. P. Turon, D. Rouan, P. Lena, J. Wijnbergen and J. W. Alders</i>	649
Operon structure of DNA transfer cistrons on the F sex factor— <i>Reiner Helmuth and Mark Achtman</i>	652

LETTERS TO NATURE

Discovery of powerful transient X-ray source A0620-00 with Ariel V Sky Survey Experiment— <i>M. Elvis, C. G. Page, K. A. Pounds, M. J. Ricketts and M. J. L. Turner</i>	656
The X-ray spectrum of A0620-00— <i>M. J. Ricketts, K. A. Pounds and M. J. L. Turner</i>	658
Observations of A0620-00 at 962 and 151 MHz— <i>R. J. Davis, M. R. Edwards, I. Morison and R. E. Spencer</i>	659
The optical counterpart of A0620-00 before its eruption— <i>M. J. Ward, M. V. Penston, C. A. Murray and E. D. Clements</i>	659
Galactic superhaloes, globular clusters and high latitude X-ray sources— <i>T. A. Matilsky</i>	660
Gas well pressure fluctuations and earthquakes— <i>F. T. Wu</i>	661
Gravitational drive on oceanic plates caused by thermal contraction— <i>C. R. B. Lister</i>	663
Coated optical guides for spectrophotometry of chemical reactions— <i>E. E. Hardy, D. J. David, N. S. Kapany and F. C. Unterleitner</i>	666
Implications of drought for vertebrate fossil assemblages— <i>P. Shipman</i>	667
<i>Hypsilophodon</i> and <i>Iguanodon</i> from the Lower Cretaceous of North America— <i>P. M. Galton and J. A. Jensen</i>	668
Membrane augmentation in freezing tolerance of plant cells— <i>J. Singh, I. A. De La Roche and D. Siminovitch</i>	669
Superoxide dismutase in photosynthetic organisms provides an evolutionary hypothesis— <i>J. Lumsden and D. O. Hall</i>	670
Cross-modal matching in the monkey after discrete temporal lobe lesions— <i>A. Sahgal, M. Petrides and S. D. Iversen</i>	672
Spatial and temporal contrast sensitivity of striate cortical neurones— <i>D. J. Tolhurst and J. A. Movshon</i>	674
Absence of fast block to polyspermy in eggs of sea urchin <i>Strongylocentrotus purpuratus</i> — <i>E. W. Byrd, Jr, and F. D. Collins</i>	675
Factors released from sea urchin eggs affect cyclic nucleotide metabolism in sperm— <i>D. L. Garbers and J. G. Haidman</i>	677
Taxis to a conjugation-inducing substance in the ciliate <i>Blepharisma</i> — <i>H. Honda and A. Miyake</i>	678
Biogenesis of chemotactic molecules by the arachidonate lipoxygenase system of platelets— <i>S. R. Turner, J. A. Tanner and W. S. Lynn</i>	680
Thymus-like lymph node in nude mice— <i>C. K. Hsu, R. A. Whitney, Jr, and C. T. Hansen</i>	681

Guide to authors

● Articles are up to 3,000 words in length with at most six displayed items (figures and tables) and may either be reports of major research developments in a subject or broader reviews of progress.

● Letters are brief reports of research of unusual and wide interest, not in general longer than 1,000 words; at most they have three or four displayed items (figures and tables).

● 'Matters Arising' permits occasional short discussion of papers that have previously appeared in *Nature*. There is a limit of 300 words.

Manuscripts may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the *Système International*. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible, $\exp(a)$ is preferred to e^a if 'a' is more than one character. Articles should be accompanied by an abstract of not more than fifty words listing the main conclusions.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) To refer to several references by the same author at once, only one reference number need be given.

(ii) Cite first and last pages.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed. (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished work' should be incorporated in the text.

Artwork should be sent with the manuscript. All artwork should be marked with the author's name. Line drawings should preferably be in Indian ink on heavy cartridge paper, although other materials are acceptable: thin, shiny, folded, torn or heavily handled material should be avoided. Matt rather than glossy photographs are preferred. Figures are usually reduced to one column width. The originals should be about as wide as a page of *Nature*. Figures, particularly maps, should contain nothing but essential material. It is preferred that the original be unlabelled, but with a copy containing lettering. Labelling on photographs should if possible be avoided entirely. We are always glad to see artwork for possible use on the cover, whether or not it is associated with a manuscript, but cannot guarantee the return of material.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

A fuller guide appeared in *Nature* (246, 238; 1973).

Unexpectedly rapid action of human interferon in physiological conditions— <i>F. Dianzani and S. Baron</i>	682
Immunity to Marek's disease induced by glutaraldehyde-treated cells of Marek's disease lymphoblastoid cell lines— <i>P. C. Powell</i>	684
Isolation of 14-nm virus-like particles from mouse brain infected with scrapie agent— <i>H. J. Cho and A. S. Greig</i>	685
Latent infection of the peripheral ANS with herpes simplex virus— <i>R. W. Price, B. J. Katz and A. L. Notkins</i>	686
Interval coding of temperature by CNS neurones in thermoregulation— <i>T. A. Reaves and J. E. Heath</i>	688
Evoked transmitter release increased by inorganic mercury at frog neuromuscular junction— <i>R. S. Manalis and G. P. Cooper</i>	690
Effect of internal fluoride and phosphate on membrane currents during intracellular dialysis of nerve cells— <i>P. G. Kostyuk, O. A. Krishtal and V. I. Pidoplichko</i>	691
Simultaneous changes in fluorescence and optical retardation in single muscle fibres during activity— <i>H. Oetliker, S. M. Baylor and W. K. Chandler</i>	693
Membrane noise in slowly adapting stretch receptor neurone of lobster— <i>L. Sjölin and W. Grampp</i>	696
Subthreshold membrane currents in slowly adapting stretch receptor neurone of lobster— <i>W. Grampp and L. Sjölin</i>	697
Plasma membrane-associated increase in guanylate cyclase activity in regenerating rat liver— <i>C. Goriadis and W. Reutter</i>	698
Increases in cyclic GMP levels in brain and liver with sodium azide an activator of guanylate cyclase— <i>H. Kimura, C. K. Mittal and F. Murad</i>	700
Positive control of cyclic AMP on mesenchymal factor controlled DNA synthesis in embryonic pancreas— <i>S. Filosa, R. Pictet and W. J. Rutter</i>	702
Ultraviolet light-induced unscheduled DNA synthesis in mouse oocytes during meiotic maturation— <i>Y. Masui and R. A. Pedersen</i>	705
Duplex microtubule is a new form of tubulin assembly induced by polycations— <i>M. Jacobs, P. M. Bennett and M. J. Dickens</i>	707
An outer component of microtubules— <i>O. Behnke</i>	709
Foetal erythropoiesis in human leukaemia— <i>D. J. Weatherall, J. B. Clegg, W. G. Wood, S. T. Callender, B. L. Sheridan and J. Pritchard</i>	710
Evidence for Hb Lepore-like hybrid globin β chain genes in mice— <i>G. Steinheider, H. Melderis and W. Ostertag</i>	712
Embryonic ϵ chains of mice and rabbits— <i>G. Steinheider, H. Melderis and W. Ostertag</i>	714
Predicted distribution of NAD domain among glycolytic enzymes— <i>E. Stellwagen, R. Cass, S. T. Thompson and M. Woody</i>	716
X-ray diffraction patterns from haemoglobin-free erythrocyte membranes— <i>J. B. Finean, R. Freeman and R. Coleman</i>	718
State of chlorine and potassium in human platelets and red cells— <i>R. J. Skaer and P. D. Peters</i>	719
Matters arising	
Interpretation of apparent ages in Minnesota— <i>J. S. Farhat and G. W. Wetherill</i>	721
Reply— <i>S. S. Goldich and C. E. Hedge</i>	722
Inhibition of Na, K-activated ATPase and release of neuro-transmitters— <i>A. G. Garcia and S. M. Kirpekar</i>	722
REVIEWS	
Beyond the Energy Crisis (John Maddox)— <i>G. R. Bainbridge</i>	723
Phytochrome and Photomorphogenesis: An Introduction to the Photocontrol of Plant Development (Harry Smith)— <i>Daphne J. Osborne</i>	724
The Shoot Apex and Leaf Growth: A Study in Quantitative Biology (R. F. Williams)— <i>John Ingle</i>	724
Image Science: Principles, Analysis and Evaluation of Photographic-Type Image Processes (J. C. Dainty and R. Shaw)— <i>Andrew Holmes-Siedle</i>	725
Principles and Practice in Modern Archaeology (David M. Browne)— <i>B. W. Cunliffe</i>	725
Biocontrol of Rodents (Lennart Hansson and Bo Nilsson, editors)— <i>Graham Twigg</i>	725
Engineering in Medicine (B. McA. Sayers, S. A. V. Swanson and B. W. Watson)— <i>D. C. Simpson</i>	725
Fracture of Brittle Solids (B. R. Lawn and T. R. Wilshaw)— <i>J. W. Craggs</i>	725

How much planning is enough?

REPORTS by the OECD on national policies for scientific research and the like have never been exactly bed-time reading for most scientists. Essential raw material, certainly, for politicians, civil servants and those who study the policies that emerge, but until recently little more than titles on a bookshelf to others. All that is changing, however, as the man on the laboratory floor increasingly realises that his own future is so inextricably bound up with the policies made in London, Paris or Washington that he simply has to take an interest.

The emergence of another weighty OECD report is therefore, perhaps, the time for a few more people to become acquainted with the kind of data on science that that organisation provides. This particular report is called *Changing Priorities for Government R & D* and, be warned, you need plenty of time (and a magnifying glass) to digest it all properly; even the authors admit that "this is by no means a short report".

One of the conclusions reached in the report, and perhaps not a very startling one, is that none of the 12 OECD countries studied had anything like a foolproof system whereby the allocation of funds and their breakdown between activities could be planned in advance through an overall 'science budget' which reflected priorities laid down as part of a government's overall policy. That may sound a laudable thing to be aiming for, until one comes to realise that some 10% of the total government expenditure on research and development in France and the UK goes to the "advancement of science via general university funds" (through the University Grants Committee in the UK), that in countries like the Netherlands, Norway and Sweden the figure is between 20% and 45%, and that in Japan it is a staggering 60+. Persuading universities successfully that such and such a list of priorities is the right one is tantamount, at least in the UK, to removing much of their autonomy, any talk of which is liable to make the new and diligent bed-time reader of OECD reports toss this latest document to one side.

This brings to mind the calls made a year or so ago by the UK Parliamentary Select Committee on Science and Technology for a Minister of Research and Development to be appointed, and the general opprobrium that was heaped on the idea. Few would support the regimentation in such a way of an area for which regimentation is so obviously inappropriate.

Leaving aside the question of whether completely planned science is necessarily good and useful science, as the OECD seems tacitly to assume, the OECD report contains some interesting revelations about the way the 12 selected countries allocated and divided up their funds for research and development. The policy-making

machinery in each country, although running true to a basic pattern, is nonetheless definitely unique, and yet most of the 12 have come to allocate much the same fraction of total government expenditure to research and development, a trend which became particularly marked in the early 1970s. In 1961, for example, the USA, the UK and Germany spent, respectively, 10.5, 8.5 and 3.7% of their total expenditure on research and development, but by 1971 these figures had become 7.5, 7.1 and 6.0%. Coincidence? Or have three quite different systems for deciding the funding of research and development come up, roughly, with the 'right' answer even in the absence of complete planning and the complete ordering of priorities.

A closer examination of the priority accorded to research and development activities such as 'civil nuclear', 'civil space' and 'defence' reveals more similarities, but also some discrepancies. For example, the authors of the OECD report have set up, for each country, a league table which places expenditures on each of 14 research and development areas in order. Comparing these league tables for the 12 countries shows that the UK, Germany, France and Italy have roughly the same ideas about how to divide up research and development funds, and that Norway, the Netherlands, Belgium and Sweden also work to their own characteristically similar lists of priorities. On a more detailed level still, however, there are of course differences even between countries with superficially similar scientific aims; France and Italy, for instance, spend 1.6 and 0.4% respectively, of total government expenditure on 'civil nuclear'. Not surprisingly, the greatest disparities are to be found in the realms of defence research, with the USA, the UK and the Netherlands, for example, spending 4.9, 2.9 and 0.3% of their total expenditure on it.

Although items such as these appear near the beginning of any government's shopping list for research, the other end of the list contains some entries which are all too often glossed over or ignored in discussing a country's research programme. One such is research and development for the benefit of developing countries. The situation is epitomised by the fact that for 5 of the 12 OECD countries surveyed, no data were available, indicating either that a negligible amount was spent or that the amounts were hard to pick out from the general research and development background (and therefore hard to plan). France and the USA spend most, some \$20 million each in 1972, which represents 1.5 and 0.2% respectively, of the total government funding for research and development—not really too impressive when the target set for the UN Second Development Decade is 5%. □

A new way to slay old pests

Tests are under way at the Microbial Research Establishment, Porton Down, to determine the safety of two viruses which may be used in the control of insect pests. News of the work, which is being carried out under contract for the Ministry of Overseas Development, was given by Dr T. W. Tinsley to members of the British Association, gathered for their annual meeting at Guildford last week. Dr Tinsley, who is Director of the Natural Environment Research Council's Unit of Invertebrate Virology at Oxford, described the potential of viral control to Peter Collins.

AWARENESS of the potential of the virus control of an insect pest dates from the 1930s. At that time, the European spruce sawfly, *Gilpinia hercyniae*, which was causing catastrophic damage to spruce forests in Canada, began to decline in numbers and within a few years was no longer an economically important pest. The reason was found to be infection by a virus, which in Europe was one of the factors controlling the natural sawfly population. But development of the possibilities opened up by this fortunate incident was delayed by the Second World War and then inhibited by the discovery of the vast range of new chemical pesticides which set the pattern for pest control in the immediate post-war era. This pattern was to last at least as long as the commercial profitability of the chemical pesticides, especially when it was found that the research required to develop viruses for this purpose was possibly as costly, and certainly as time-consuming, as the development of new chemical agents.

There are several reasons why the situation has changed in recent years. Initially, increasing resistance on the part of pests of agricultural as well as medical importance drew attention to the advantage of all types of biological control. Further pressure in the same direction resulted from increased concern at the environmental effects of many "classical" pesticides. More recently, two even more potent factors have given impetus to all research in this field: first, the growing serious-

ness of the world food situation, and hence the urgent need for more efficient control of all manner of pests and diseases, and, second, the enormous and sudden rise in the cost of all chemical products.

The part that may be played by viral agents in this new era of pest control, and the reasons why the advance into this field must be gradual and cautious were clearly stated by Dr Tinsley in his contribution to the symposium on the work of the research councils at Guildford last week. As Director of NERC's Unit of Invertebrate Virology (UIV) at Oxford, Dr Tinsley indicated what has been achieved so far and gave some idea of what may be expected in the next few years, at least within the unit's terms of reference.

For reasons of safety, and in particular because of the risk of cross-infection with higher animals, the WHO and the FAO have recommended that among the seven groups of viruses known to occur in insects, only the baculoviruses should be considered as pesticidal agents. So far as is known, these have neither chemical, physical nor biological properties in common with any virus found in vertebrates or plants, thus limiting the risk of cross infection to other insects or, at worst, invertebrates. Within this group, the unit's work is at present concentrated on the nuclear polyhedrosis viruses (NPVs) which attack four members of the Lepidopteran genus *Spodoptera*. The larvae of these Noctuid moths are now among the world's most serious pests, attacking a wide range of important crop plants from grass to fruit trees in Asia, Africa and across the Atlantic. In particular, interest has been concentrated on *S. exempta*, the East African army worm, possibly the world's most serious grass-land pest. Able to produce up to 11 generations in a single year, it is found from southern Tanzania to Ethiopia, and its outbreaks have been known to denude up to 300 square miles of pasture in a few weeks. Not surprisingly, this work is being actively supported by the Ministry of Overseas Development (MOD), and the unit works in close collaboration with MOD's Centre for Overseas Pest Research.

One of the major problems in the use of viral pesticides hitherto has been the lack of precise information about the nature and characteristics of the viruses being used, and it is towards filling this gap that the unit's programme is directed. Its prime objectives were defined by Dr Tinsley as "the investigation of the chemical, physical and biological properties of insect viruses, and then determination of the effects on the insect hosts and the manner in which the viruses spread under natural conditions". The first of

these objectives involves fundamental research in a field where little such work has been done, and in fact the unit is here leading the world.

To be of value in developing any virus as a biological control agent, four distinct steps have to be taken, and these too have been precisely defined. They involve:

- The isolation, purification and detailed characterisation of each virus in such a way as to enable its unequivocal identification. (It is surprising that this has not even been done previously for the viruses which are already in use as pest control agents in various parts of the world.)

- Testing the purified virus under laboratory conditions to assess its efficacy and establish its host range.

- Testing the toxicological properties of the virus "together with any associated formulative materials". This must be accompanied by investigation of the possibility of infection of, and replication in, non-target invertebrates and vertebrates.

- Field trials, on an increasing scale, on the crop and in the areas in which it is intended to use the virus as a pesticide. To do this final step satisfactorily, some system of monitoring needs to be evolved, and such monitoring will have to be continued for several years. It is thus apparent that the whole process is a lengthy one, and any idea that viral pesticides can provide an immediate panacea, even within the range of pests against which their use is intended, has to be forgotten.

Only the first two steps are the responsibility of the UIV at Oxford, and already some of the results are apparent. Thus, examination of the viruses of the four species of *Spodoptera* has indicated that these viruses, although each distinct and recognisable, fall into two groups or serotypes, each with several closely related strains. This has gone some way towards answering the question whether or not, as has hitherto been taken for granted, insect viruses are specific—a matter of the utmost importance if any such virus is to be widely distributed in a natural environment. Moreover, again to quote Dr Tinsley, "this is the first time that such a detailed investigation has been undertaken and also the first time it has been possible to make unequivocal identifications of any of the baculoviruses". Moreover, until this had been done, "it was not possible to be certain that the host insects had died from the test virus, from a second unrelated virus which occurred as a latent infection, or from a cross-contamination"—points that have needed to be ascertained before the second step could be undertaken with any confidence.

When sufficient purified and identified material of any of the viruses is available, it passes to the Microbiological Research Establishment (MRE) at Porton, working under contract from the MOD. One of the problems that is arising at this third stage is that although the MRE has the necessary facilities for undertaking any tests that may be required to check the toxicity of the viruses for vertebrates, their staff have no experience in handling, or working with, insects—and any results from Porton will need to be checked against the insect host. Arrangements are therefore being made, with the cooperation also of the Medical Research Council, for the closest possible collaboration between MRE and UIV at this stage. Only when a virus has been cleared of any potential ecological hazard at the laboratory level can the fourth stage of field testing, in the areas where its use is envisaged, be started. The first candidate to reach this stage is likely to be the virus affecting *Spodoptera exempta*, if only because of the MOD's very special interest in protecting the grasslands of the Commonwealth countries (and others) of East Africa. Meanwhile, however, research into the ecology of an active, natural outbreak of an insect virus is also being carried out by staff from the UIV. The insect concerned is, again, the spruce sawfly, *Gilpinia hercyniae* an outbreak of which was identified some years ago in the Forestry Commission's Hafren Forest in Montgomeryshire, UK. Dr Tinsley was already applying for permission to experiment with the relevant virus at Hafren, when, in 1970, a natural infection was discovered in the forest, which thus became an ideal field laboratory for research into the ecology and epidemiology of a natural insect virus outbreak.

Although in the UK this fundamental approach to the development of viral pesticides has been adopted and is being rigorously pursued, the same is not true elsewhere. Viral pesticides have for some time now been on the market in the USA and they are known to have been used extensively for some years in the USSR, particularly against pests of forest trees and certain industrial crops. What is happening in Russia is not at all clear, nor is it known what precautions are taken or what problems, if any, have arisen. But certain of the difficulties that the pesticide industry may face, when it comes to commercial production of a virus that has successfully passed through all four preliminary stages, have recently become evident from American experience. The viruses concerned are again those affecting certain lepidopterous larvae, namely the genus *Heliothis*, including

H. zea (on cotton, and probably the UIV's next target insect), *H. virescens* and *H. armigera*, pests of tobacco and maize respectively; the area on which *Heliothis* NPV has been used is said to be as much as five million acres. Successes in field trials on a vast scale led, in 1971, to a "temporary exemption from tolerance requirements" on the part of the ES Environment Protection Agency, and when this was later confirmed, the way was clear to go ahead with commercial production. Two companies, International Mineral Corporation and Nutrilite, put viral pesticides on the market—Viron and VHZ respectively—confident that they had at last achieved a breakthrough. Prolonged testing and field use had indicated that the degree of control was at least as good as that with chemical insecticides, whereas after 12 years of experimentation there was said to be no change in the specificity of the virus and no sign of any resistance on the part of the host. And yet, within recent months, the product actually put on sale has seemed to be less effective than those years of testing had led the manufacturers to believe. The extent to which this is so, why it should be, and how it can have happened, is not clear.

While these and other developments are going ahead in the UK and the USA, no one, in the UK at least, believes that rapid and sensationally successful control of the target pests is just around the corner. Problems will certainly arise at higher altitudes for example, unless some way can be found of getting over the undeniable fact that NPVs are inactivated by ultraviolet light (although one recent report indicated the reverse effect for the virus of one Lepidopteran, *Autographa californica* at least when grown *in vitro*). Then there seem to be problems relating to the effect on the virus of various leaf surfaces. A great deal of work will have to be done on the evolution of suitable formulations for large scale manufacture and application of the commercial product—especially in view of recent American experience. Finally, there is some uneasiness about the adequacy of the protocols for safety testing, so far developed by the WHO on the basis of those used at present in the United States—and themselves developed for non-replicating, easily identifiable chemical pesticides.

But once these new pesticidal agents become available, unequivocally identified and rigorously tested, in standardised formulations that can be used in complete safety, a new and most powerful weapon will be available against many of the pests that threaten the world's essential food supplies and industrial crops □

KENNETH MELLANBY

Mathematics out of molehills

THERE is generally an optimum period for any worker to continue in a particular field of research. It takes a little time to become familiar with a new topic, productivity may then build up, but eventually he becomes stale and the "law of diminishing returns" seems to ensure that progress becomes slower and slower. This is the time to change direction, though after a fallow period the field may once again become productive.

These musings were prompted by a reader who writes: "Last week I was staying on a farm and looked at mole tracks as the moles went about ruining a newly seeded lawn. Why do the tracks so often run at right angles; they seem to turn through 90° at various points along their track. Perhaps they are particularly geometric beasts". Now I have been interested in moles for years and have even produced a monograph on the subject, but familiarity has evidently prevented me from recognising the interest of the tunnel pattern. My immediate reaction on receiving the letter was to go out and see what wild moles were actually up to. I looked with new interest at the working in my own garden, four acres of near-wilderness where wildlife is encouraged. I also returned to my main study area, Monks Wood National Nature Reserve. I may perhaps remind readers that moles, like most of our native fauna, are primarily woodland creatures, though they have been able to adapt to man-made habitats like farmland and lawns. I found everywhere, and clearly recorded in my own data made in previous years in farmland, that they do indeed have a predilection for right angled bends in their tunnels, particularly in new excavations in cultivated soil. In the wood, where they live in permanent tunnels which house generation after generation of solitary moles, this pattern is not so noticeable, possibly because of modifications over the years where repairs have been executed.

Another observation revealed something which may also be a function of

I write to you from a Soviet camp for political prisoners, located in the Lesnoy Settlement in Mordovia (Camp ZhKh-385/19). The problem to which I would like to draw your attention is of vital interest not only to me personally, but also to a large number of Soviet political prisoners—scientists who are in camps for expressing their political views openly.

In this letter I will not concern myself with whether and up to what extent the persecution of citizens for exercising their right to free speech, guaranteed to them by law, is lawful and justified, though this fact in itself should also come to the attention of world scientific opinion. However, this question is too vast for a thorough examination in a letter. Furthermore, it is up to each individual scientist to decide whether he wishes to express himself on this subject or not.

I would only like to draw your attention to the conditions in which these political prisoners are held and how this affects their professional skills. Among us there are physicists, mathematicians, biologists, civil engineers, philologists, philosophers and many others. Personally, I am an astronomer, specialised in the field of meteoric astronomy and astro-biology. Each one of us, regardless of his political views, remains, above all, a scientist and aims to preserve his professional skills under any circumstances.

However, this is impossible under the conditions which prevail in the camp. A specialist who is sent to a camp is deprived of the opportunity to follow developments in his field effectively. In accordance with Soviet law, to receive literature, periodically or in any other way, published abroad is categorically forbidden. This ban extends to

literature of non-political content, including specialised literature and literature published in countries on friendly terms with the USSR. Subject to so many restrictions and in practice totally isolated from any source of information, a scientist soon feels he lags behind contemporary science and that he is losing his professional skills. In accordance with existing forms of evaluation, total disqualification is reached in approximately three years.

Letter from the Soviet Union

We are serving sentences of five, seven years and longer. We face total creative impotence. We are not just deprived of freedom for a given period of time. We are deprived of our chosen work and our profession forever.

These restrictions are imposed not only on publications from abroad. Literature published in the USSR can be received only through specialised shops, which deal by post. According to the rules operating the book market in the USSR, in practical terms this means that one can acquire literature which has been published only recently and even then only if it is in small demand and cannot be sold over the counter. Any monograph or reference book indispensable to work which has been published a few years back is impossible to acquire. To receive literature from private individuals (even from relatives) is strictly forbidden. Fear of the written word reaches such proportions that even cuttings from the Soviet press are not allowed in the mail. To receive scientific infor-

mation in private letters from colleagues—such a fashionable method during the Renaissance and widely used at present—is also impossible for us. Probably as a result of inadequate education of those who guard us during our imprisonment, letters of such 'strange' content arouse special suspicion. Their censoring takes many long months and quite often they are not even delivered. Letters from abroad excite particular apprehension.

The disqualification of scientific workers is speeded along by purely physiological reasons. We are all forced to do heavy physical work, and many of us who are no longer so young are badly equipped for it. This leaves us no time or energy for intellectual pursuits. The food is highly insufficient, low in calories and in quality (lacking in protein, carbohydrates, phosphorus, vitamins). A condition of semi-starvation is normal for us. I will not dwell on this problem further as it has already been examined repeatedly. I will only add that all this contributes in bringing about a sharp decrease of intellectual potential, and a weakening of memory, and so on.

For the sake of humanity and professional solidarity, I beg you, and through you scientists throughout the world, to intercede on our behalf in this difficult situation. I appeal to you to focus your attention on the plight of your colleagues. There is no need for political action. We only ask you to secure for Soviet scientists the right of unhindered use of scientific literature, and the right to maintain scientific contacts. Please send your colleagues in prison camps books and journals and other scientific material, and in this way ease the conditions in which they are held. —K. A. Lyubarskii

this same geometrical behaviour. Monks Wood consists of blocks of woodland, divided by grassy rides of short turf. The moles spend most of their time in an anastomosing network of permanent burrows under the trees, but this system is joined at frequent intervals by mole runs which cross under the rides. These almost always run straight across the ride; they never run along it. And the burrow comes out of one woodland block and enters the other, at almost exactly ninety degrees.

How and why this happens is difficult to understand. Why does the mole never make a right-angle under the woodland ride, which may be several yards across? Under a lawn, which the ride resembles, a zig-zag would normally occur in this distance. A mole busily burrowing underground in the wood

must, somehow, recognise that it has reached the edge of the ride, and it must receive some stimulus which causes it to burrow in a particular direction towards some goal on the other side.

My correspondent raised another, more familiar, problem. He asked: "How can one decently remove moles when they are wrecking your lawn without actually putting them to death?" This is difficult, and I usually try to persuade people to learn to live with their moles. Especially in a clay soil a mole (there is usually only one at a time in the average garden) makes a series of hills from the spoil as it digs its tunnel system, but when this is complete there is little further evidence of its presence. The mole is territorial, and will keep other individuals away.

There are various repellants on the

market. If they work, they usually divert the animals to a neighbour's garden. Generally they are unsuccessful, or they only close up a section of the burrow system. The Caper Spurge, as attractive plant in its own right, is reputed to keep the garden free, but it seldom does.

If people must be rid of moles, they have to kill them. The commercial scissor trap will catch one troublesome beast, and worms baited with strychnine will wipe out a large population. But the garden, particularly if adjacent to a wood, will always be liable to re-invasion. The same will happen if the neighbours find an effective repellant! It is best to rely on the territorial instincts of your own moles, hoping that they will do little more damage and will keep out all other members of their own species. □

international news

Tbilisi: a conference with problems

from Vera Rich

THE problem of the participation of Soviet scientists in international conferences is a long-standing one, and organising secretaries have for many years had to deal with the problem of delegates who are refused visas and substitutes who have little or no knowledge of the subject concerned but who are "approved" by the Soviet government. The case of the International Conference on Artificial Intelligence at Tbilisi this week raised the problem in a particularly acute form. Since the venue of this conference was in the USSR, the difficulties over visas and "exit dossiers" could not arise for would-be participants within the Soviet Union. Nevertheless, several Jewish refusnik scientists have been prevented from attending.

Professor Aleksandr Lerner was informed on June 5 by the KGB that it regarded the invitation from the Programme Secretary of the Conference, Professor Patrick Winston, as an "American provocation". Since then Professor Lerner has been called in by the KGB and questioned for several hours in connection with his invitation to the conference.

Another would-be participant, Ovsei Gel'man, received his long-awaited visa for Israel just in time for him to be safely out of the Soviet Union before the conference began. On reaching Vienna, he disclosed the remarkable piece of information that the physicist brothers Isai and Grigorii Goldshtein, who, being residents of Tbilisi would not have to obtain any travel or residence clearance to attend the conference, still had no idea at the end of August that they had been invited. It should be noted that these tactics of exclusion originate from the KGB only; the "establishment" Soviet scientists themselves have made no objection to the participation of the refusniks.

The Tbilisi conference has been used by more than 70 academics from British, US and Canadian universities as an occasion to protest against the treatment of Soviet scientists Valentin

A NEW Soviet base is to be established in Antarctica this year to prospect for mineral resources on the continent. Manned by a research team of 50 geologists, geophysicists and cartographers the station, called Druzhnaya Amity, will be based on the Filchner Ice Shelf at the southern end of the Weddel Sea, a region that until now has received scant Soviet attention.

According to an announcement from the official Soviet news agency, Tass, exploration will extend from the Antarctic Peninsula to Queen Maud Land, crossing an area which, until territorial claims were suspended by the Antarctic Treaty in 1961, was a part of the British Antarctic Territory that had also been claimed by both Argentina and Chile.

There is little room for doubt that the prime objective of the new Soviet team will be to prospect for mineral resources, with oil, gas and copper as the main targets. The Tass announcement stated that "the south [of the region to be surveyed] is reminiscent of the ore bearing zones of Siberia, while the west is a continuation of the American mountains [Andes] famous for their deposits of non-ferrous minerals.

"The most extensive region of continental shelf in Antarctica, a potential natural storehouse of oil and gas," the statement continued, "extends across the Weddel Sea and the Filchner Ice Shelf". Significantly, Soviet interest in Antarctica has in the past been concentrated largely on the opposite, eastern side of the continent.

Although official sources in Britain deny that there is any significance in the timing of the announcement, which followed closely the eighth Consultative Meeting between the signatories to the Antarctic Treaty in Oslo, it may force a decision on the

outstanding problem of the commercial exploitation of Antarctica. The Oslo meeting, which ended on June 20, was the first at which the signatories confronted that issue face on, and they were unable to reach any final decision. It was, however, agreed that the matter would become the subject of exhaustive international investigation involving all 13 signatories, and to that end a meeting is to be held in Paris in 1976 in preparation for the 1977 Consultative Meeting in London.

The Soviet decision to press on with preparations for eventual commercial exploitation may, however, precipitate a more positive response because of the new station's location. Sovereignty over the Filchner Ice Shelf was formerly the subject of an unsettled dispute between Argentina, Britain and Chile, and though territorial claims are suspended under the treaty, awkward legal questions would emerge should the Soviet Union uncover commercially exploitable resources in the area.

The decision to establish the base does not apparently run contrary to the Oslo recommendations and it is unlikely that the Soviet government will act to contravene the terms of the existing treaty. Though a solution to the problem remains some way off, there are indications that the signatories may eventually reach a mutually acceptable solution within the treaty, particularly as they are reluctant to throw the matter open to broad international debate. It is, therefore, likely that the Soviet Union, while attempting to forestall further prevarication on an issue of growing concern, will uphold the treaty; certainly, there is no reason why under its terms they should not establish a base in what was once British Antarctic Territory.

—Allan Piper

Turchin and Leonid Plyushch. The Western group, which includes many eminent names in the field of artificial intelligence, have petitioned the Soviet Academy of Sciences, Premier Brezhnev, Procurator General R. Rudenko and a good many more prominent officials. Noting that Turchin and Plyushch have been dismissed from their jobs and harassed "for defending the freedom of their colleagues", the

signatories proclaim Turchin's dismissal as "inexcusable" and Plyushch's hospital detention and drug treatment as "horrificing".

"We want to make it clear", they add, "that scientists around the world, and in particular members of the Artificial Intelligence community, have taken a keen interest in the fate of these men, and strongly protest against the treatment they have received."

Turchin is a cybernetician and physicist responsible for designing and implementing the language REFAL, which is used for designing other languages and for proving the correctness of programs. Jointly with Andrei Sakharov he co-authored a memo on human rights and social problems in 1970, and in September 1973 he circulated an open letter protesting against the official harassment of Sakharov. This led to his expulsion from the Moscow Institute for the Automation and Construction Industry in July 1974.

Leonid Plyushch, whose case has already been reported in *Nature*, was dismissed from his job at the Cybernetics Institute of the Ukraine Academy of Science after publishing a letter of protest against the trial of Yuri Galanskov and Alexander Ginsburg. He was arrested in January 1972 on charges of anti-Soviet activity and, after examination at the Serbsky Institute of Forensic Psychiatry, was diagnosed as suffering from "creeping schizophrenia with messianic and reformist ideas." He was not allowed to attend his own trial in January 1973, when it was decided that he should be detained in a psychiatric hospital. He remains there.

● Following the prestigious success of the Soyuz-Apollo project (at least as a publicity venture in support of detente and cooperation), the Soviet Union is pressing forward with a number of other international projects. At the beginning of August, the coopera-

tion of the space mission was repeated on a smaller scale with a joint stratospheric probe, consisting of two canisters of instruments—one Soviet and one American—mounted on a single triangular frame and carried aloft by an automatic balloon system. The apparatus, launched from a site near Ryl'sk in the Kursk region, reached an altitude of 30,000 m before descending by parachute, and the whole flight, from launch to sighting by the recovery helicopter, lasted 142 minutes. The purpose of the experiment was investigation of the stratosphere and the effect of stratospheric processes on climate and weather.

This, however, hardly seems a field in which a joint flight is needed—surely as much would have been achieved if the Soviet team had made the results of their research available to the Americans? The only purpose for such a joint flight would be the joint calibration of two sets of instruments preparatory to a full programme.

● Some cooperative ventures, of course, clearly demand the participation of all partners. Thus the programme of seismic sounding of the Pamir-Himalaya fold, using charges of TNT exploded under the Kara-Kul' (USSR) and Attok (Pakistan) salt lakes, and at the foot of Mt Nanga-Parbat (India) is a clear case for participation by scientists of the countries concerned. During the 1974 tests all three countries were, indeed, represented. In the latest set of soundings (last month), however, a further parti-

cipant was added—Italy. It is difficult to find an explanation for this addition, other than at the diplomatic level. Italy is not particularly noted for work in seismic sounding and, to date, the principal Italian interest in the Himalayas has been that of mountaineering. The participation of individual scientists in the research projects of other countries, particularly when their own does not support a similar programme, has long been urged as a productive means of international cooperation in science. The Soviet system of centralised control of science means, in effect, that any such participation must be approved by the relevant government department, and therefore is apt to be presented to the world not as the small number of foreign scientists joining a given research team but as a major diplomatic issue.

● The influence of the Lysenko period in Soviet biology still, from time to time, appears in scientific and popular articles. One such echo of the past appeared in a recent *Pravda* story (August 25, 1975) on the "Party news" page, describing the heavily laden orchards attached to the Bryansk Machine-construction Plant. These orchards, it is claimed, "were originally planted with the participation of I. V. Michurin. The workers of the Bryansk plant turned to him for advice on how best to grow fruit trees." Michurin was, in fact, noted for his work on the acclimatisation of fruit trees, although many of his methods savoured of folk lore (watering the trees with sweetened water to teach them to bear sweet fruit, for example), but after his death in 1935, when Lysenko claimed him as a forerunner of his own peculiar views on plant selection, the name Michurin became synonymous with the anti-heredity school of biology. At a time when a new drive is being made in Soviet research towards investment of time, funds and talents in molecular genetics, the reappearance of the name Michurin, cited without explanation, as a kind of cult-figure to whom the success of the trees is attributed, strikes a somewhat odd note.

● The latest monitoring device recommended by Soviet experts on radioactive pollution in seawater is the sprat. According to the findings of an extensive study made in the Atlantic and off-shore seas of Europe, the sprat is highly sensitive to products of radioactive decay possessing a long half-life, notably caesium-137 and strontium-90. According to the research team, the sprat absorbs even microscopic admixtures of these isotopes quantitatively, with an accuracy comparable with that of the latest electronic equipment. □

BECAUSE of a failure on the part of its international Board of Management to agree on the future funding of the OECD Dragon High Temperature Reactor Project, formal steps will have to be taken early this month to run the project down. Formal, because nobody really thinks that an agreement will fail to be struck before notices to many of the 320 people who work on the project (most of them seconded from other organisations) expire in December.

Much of the blame for the delay, it seems, falls squarely on the British Department of Energy which is dragging its heels on the grounds that work on high temperature reactors (HTRs) has, as far as the UK is concerned, been overshadowed by the decision to go for the steam generating heavy water reactor as the basis of the next generation of nuclear power stations. The department is reluctant to continue contributing some £1.4 million a year to Dragon through the UKAEA, even though there is a considerable hidden bonus in that the UKAEA itself claws back £2.1 million a year from the Dragon Project (total budget £3.8

million a year) for services and so on provided at Winfrith, Dorset, where the Dragon reactor is situated. It is not clear that the overall costs of Winfrith could be cut by nearly £2.1 million a year if Dragon were to disappear.

Dragon has been running for 11 years during which time it has provided valuable operating experience of high temperature reactors both for the seven members of the project (six European countries together with Euratom) and for countries like the United States, where General Atomic, for example, is actively interested in commercial HTRs. Also, recently, there has been a surge of interest in the use of HTRs as sources of process heat for the chemical and steel-making industries. European steel-makers have even formed themselves into the European Nuclear Steel-making Club (ENSEC).

Clearly the UK's partners in the Dragon Project see it as a useful thing to persevere with for a further five-year period, though admittedly the UK itself might reasonably hope for some token reduction in the fairly large share of the bill which it picks up at present.

—Roger Woodham

W. C. FIELDS once remarked that when he visited Philadelphia, it was closed. The same remark could equally well be applied to Washington during the entire month of August this year. Congress has been out of action, President Ford and some of his top advisers have been taking things easy in Colorado, and many federal bureaucrats have been off on their summer holidays, leaving the tourists to face a heat wave and record-breaking pollution levels. The big news story has been whether or not oil prices will be decontrolled, and many esteemed journalists have been driven to writing about how dull it all is. Quite a change from last year.

But at least one body has been keeping busy. The International Cultural Foundation, an organisation linked to the Rev. Sun Myung Moon, a millionaire evangelist from South Korea, has been putting together a meeting called the "Fourth International Conference on the Unity of the Sciences", and a glittering array of scientific and academic talent has been signed up to take part in the event. The conference, which is set to take place at the Waldorf-Astoria Hotel in New York on November 27-30, is already generating some controversy.

A similar gathering was staged in London last year. It was also stiff with Nobel Laureates and it, too, generated considerable controversy because of Moon's association with the event.

Moon is the founder of the Unification Church, a religious cult founded on an anti-communist philosophy, and supported by street-corner fund raising and by the profits of several Korean industries. Moon, who is said to be close to the South Korean dictatorship, generated some attention last year when he led his followers in prayer on the Capitol steps for the political survival of President Nixon. And his church has recently been in the headlines thanks to a court suit brought by the parents of a teenage girl who are attempting to reclaim their daughter from its clutches. They claim that the church has so much psychological influence over her that she cannot exercise her free will.

The Fourth International Conference on the Unity of the Sciences has, however, attracted a list of sponsors and advisers which reads like a page out of the *Who's Who* of science. A letter sent with invitations to the meeting lists as chairmen or advisers Eugene Wigner, Alvin Weinberg, Kenneth Mellanby, Edward David, Werner Heisenberg, C. P. Snow, Jean Piaget, Julius Axelrod, Herman Kahn, Jonas Salk, and many others. But, according to an article in *Science and Government Report*, several of the participants listed in the letter are considering drop-

ping out. They were either unaware of Moon's connection with the International Cultural Foundation when they accepted invitations, or they are simply having second thoughts about being associated with an event sponsored by Moon's organisation. Similar problems arose with the London meeting last year.

Discontent about Moon's sponsorship of the conference has prompted section chairmen to send a letter to other participants assuring them that the International Cultural Foundation will not interfere in the conference, and that participants will be free to express their own views.

Washington seen

by Colin Norman

But the letter hasn't stilled the discontent and more dropouts can be expected.

● Congress reassembles this week, prepared to do battle with President Ford on oil prices and various other matters. In between the skirmishes, it may get round to passing a bill to re-establish a science policy office in the White House. There has, at least, been some discernable progress on that measure.

Last month, on the eve of the Congressional recess, Representatives Olin Teague and Charles Mosher, respectively the chairman and senior Republican on the House Committee on Science and Technology, jointly introduced a bill which is likely to be passed by the House with little change. The measure is similar in many respects to President Ford's proposal, although it spells out the duties of the office in some detail, and it is prefaced by a

lengthy discourse on the objectives for a national science policy.

The bill would establish a White House Office of Science and Technology Policy (OSTP), headed by a director who would double as the science adviser to the President, and four deputies. Its chief task would be to provide advice to the president on "scientific and technological considerations involved in areas of national concern, including, but not limited to, the economy, national security, health, foreign relations, the environment, and the technological recovery and use of resources. It would also be required to help in the preparation of the federal budget, and "assist the President in providing general leadership and coordination of the research and development programs of the federal government". The bill does not state how the office should function within the White House, however, leaving such arrangements for the President to determine.

One item in the bill which was not included in Ford's proposal is the setting up of a Presidential commission, consisting of between 5 and 12 scientists, to carry out a 15-month study of the federal government's science and technology programmes, and to recommend ways in which the overall effort can be improved.

The bill is expected to be passed by the House Science and Technology Committee later this month, and by the full House in October. Meanwhile, the Senate Committees on Labor and Public Welfare, Science and Astronautics, and Commerce, which all have jurisdiction over the bill, will probably hold hearings later this month.

One factor which could upset the timing however, is that Teague was taken ill last month with what was believed to be a stroke, and although he has been discharged from hospital, it is unclear whether his committee schedules will be affected.

● The National Science Foundation (NSF) which has been having severe political problems with critics in Congress, has so far been let off lightly. An amendment designed to give Congress power to veto any individual NSF grant before it is awarded, which was attached to a bill earlier this year by the House has finally been discarded completely. The final version of the bill was passed without the amendment last month and sent to President Ford. ● Finally, the Atomic Safety and Licensing Board has demonstrated a fine sense of irony. It has scheduled a hearing on the proposed demonstration liquid metal fast breeder reactor, which has broken all records for cost overruns, in the US Bankruptcy Courtroom.

Spoon bending: an experimental approach

SIR,—We have investigated six young people who claimed the power of bending objects by stroking in the manner demonstrated on television recently by Uri Geller and others. In this report we will call these people A, B, C, D, E, and F. A, B, and F are young girls all aged eleven years. C is a girl of thirteen, while D and E are boys aged ten and eight respectively. All were contacted with the aid of local press and television. A, B and C had received publicity in the local evening papers. Subsequently Dr Pamplin appeared on BBC "Points West" local television news programme when B demonstrated her ability quite convincingly. The parents of D, E and F subsequently contacted Dr Pamplin claiming that their children could also bend cutlery by stroking.

Most of the subjects were first visited in their own homes where they showed their ability in the casual atmosphere of their sitting rooms. A succeeded in bending a weighed and measured rod of mild steel of 3/10ths inch diameter supplied by the experimenters as well as her own cutlery.

All six subjects were subsequently tested in Bath University's psychology laboratory. This laboratory has three large one-way mirrors behind which the experimenter can observe, photograph and take television video tape unseen by the subject. In all cases, except A, one or more observers sat in the laboratory with the subject. In the first four experiments there was a second television camera in the laboratory with the observers. The subject was handed the spoon or rod after its outline had been drawn on a sheet of paper and was allowed to stroke it in the approved manner between forefinger and thumb of one hand and to report what they felt was happening. B reported that the spoon "felt soft" before bending. C stated that it "felt like plaster, then running water". The running water feeling occurred, it was said, just before bending occurred. However, at no time did C bend anything for us while experimenters were watching. The others all succeeded in bending spoons and B bent a rod of mild steel as well.

The aim of the experiment was to obtain a photographic or video taped record of the actual moment of

bending. The observer in the room measured the spoon against its outline at intervals during the session noting the time.

The observers in the room were instructed to deliberately relax their vigilance at intervals after the first twenty minutes. The experimenters were specially alert during these periods and in all cases except C they observed and photographed cheating by the subjects. A put the rod under her foot to bend it; B, E and F used two hands to bend the spoon using considerable muscular power, while D tried to hide his hands under a table to bend a spoon in both hands out of sight of the observer.

We can assert that in no case did we observe a rod or spoon bent other than by palpably normal means. We cannot, of course, conclude that all instances of the so called Geller Effect are due to cheating. However we offer details of our experimental procedure in the hope of helping other experimenters design experiments that can be used when cheating is suspected.

Presto! Would you believe?

SIR,—In his review of John Taylor's book, "Superminds", Dr C. Evans comments on the ease with which the author seems able to discount the possibility of fraud and deceit on the part of the children involved in purported "psychic" performances. I recently launched an experiment with a newspaper which reports psychic phenomena to prove that persons lacking expertise can easily be deceived by a person using very simple methods—if the predisposition to belief is there. I am a professional conjuror, and needed only modest skills to convince the newspaper that I was indeed possessed of very strong paranormal abilities. It was only necessary to claim genuine powers for the observer to relax completely and believe all.

The need to have a competent conjuror present at performances of this nature is very evident. Otherwise, the observations are of no value scientifically.

Publishing problems

SIR,—I wish to draw your attention to the difficulties which Czechoslovakian scientists seem to be encountering when publishing in international journals.

From a letter which I received from one of our contributors I learn that a paper sent to him arrived in Prague on April 7, 1975, but the author did not receive it until May 23, 1975. Furthermore, he was "commanded out" of Prague on May 24 for two weeks.

I am wondering what these ominous words "commanded out" actually mean. As fellow scientists, we have all been deeply conscious of the treatment received by some of our colleagues in Russia, who have been "frozen out" or even interned.

Let us hope that the Czechoslovakian government will not resort to Soviet methods and will continue to allow their talented scientists to publish in international journals.

JØRGEN CLAUSEN

Neurobiology,
Copenhagen, Denmark

Additive safety

SIR,—“We tend to trust Mother Nature, and suspect the organic chemist”, says Thomas Jukes mockingly in his vivid defence of synthetic food additives August 7. There is, of course, a reason to trust natural food better than food additives which must be familiar to the author of *Molecules and Evolution*: Organic chemistry happens to be 147 years old; man is at least 1×10^6 years old, and has thus fed for 999,853 years on natural food. The fact that man has survived all these effects of “numerous chemicals (in natural food) that are all more or less toxic” does not prove at all that there will be some fittest to survive the ingestion of at least as many food additives introduced mostly in the past 10-20 years.

Indeed, we do not know whether sodium benzoate has some disagreeable effects within 3 or 10 generations, whereas sugar (“one of the most ancient and universal of food preservatives”) has passed the most rigorous toxicological test there is: time. Besides, sugar tastes better.

news and views

STARTING, paradoxically, with invisibly faint electron micrographs of purple membrane patches from *Halobacterium halobium*, Nigel Unwin and Richard Henderson have reconstructed the first distinct electron images of the polypeptide chain packing inside a protein molecule (see page 28 of this issue of *Nature*). This breakthrough at the MRC Laboratory of Molecular Biology in Cambridge is a dramatic culmination of the electron micrographic "crystallography"—or Fourier microscopy—developed there by Aaron Klug and his colleagues over the past decade.

Unwin and Henderson's technique opens up a new frontier in the exploration of the internal structure of proteins—particularly those which build periodic cellular assemblies unsuited for X-ray diffraction crystallography. No one name has yet been devised to identify their method but it can be described as high-resolution, low-dose, under-focus phase-contrast, three-dimensional electron microscopy of thin, unstained, periodic biological specimens.

Drying, staining and electron irradiation can pretty well destroy the molecular order in proteins. Until now significant detail finer than about 20 Å in biological structures has rarely been revealed by electron microscopy even though good microscopes can give 3 Å point-to-point resolution. Unwin and Henderson have mitigated the trauma of dehydration on their specimens by the clever trick of replacing the water with glucose syrup (*J. molec. Biol.*, **94**, 925; 1975). Electron diffraction patterns from their sweetened purple membranes and thin catalase crystals demonstrate that periodic order is preserved out to 3.5 Å spacing, as long as the radiation dose is less than about 0.5 electrons Å⁻². They have obtained micrographs at 7 Å resolution by leaving out the stain which eliminates the usual source of contrast, and by cutting down the electron dose, which raises the noise level well above the signal. Fourier transformation is crucial for correcting, averaging and recombining the invisible microscopic images.

Contrast is produced in the micrograph of the transparent object by underfocusing. But this phase contrast oscillates between positive and negative with increasing spatial frequency, so compensation is essential to recover an undistorted image. The focus is restored using the Fourier processing

Distinct images from invisible micrographs

from D. L. D. Caspar

method previously applied to negatively stained specimens: the computed Fourier transform of the featureless low-dose micrograph—which shows sharp diffraction maxima from the regular lattice—is divided by the modulation transfer function to obtain the correct phases of the object with maximum contrast. The nodes of the transfer function are measured from the optical diffraction pattern of a high-dose micrograph which displays the contrast oscillations although the specimen itself has been incinerated.

At the safe dose for the 7 Å resolution image, only about 25 electrons on the average pass through each 7 Å × 7 Å square of the specimen. Since the difference in the number of electrons forming dark and light regions of the image at maximum phase contrast is less than 1%, the local statistical fluctuations in the micrograph are much larger than the signal. The weak signal from the periodic object is extracted from the noise by averaging over some thousands of unit cells. Evaluation of the corrected Fourier transform at the reciprocal lattice points and retransformation effects this averaging to give an in-focus projected image of a single unit of the real lattice. This is the essence of the optical filtering method: the larger the number of regularly arranged units in the lattice, the sharper the diffraction spots and the weaker the periodic signal in the image which can be distinguished from the noise whose transform extends throughout reciprocal space. The intensity of the spots is actually measured from the electron diffraction pattern of the periodic specimen, but the indispensable phase information is obtained by computation of the compensated Fourier transform of the low-dose, under-focus image.

Tilting the purple membrane lattices provides projected views from different directions which are recombined using the Fourier method of three-dimensional image reconstruction. Correcting for defocusing from large tilted specimens and refining the phase calculations to the same origin for

different views presents special problems which have been resourcefully solved by Unwin and Henderson. The maximum angle of tilt for these micrographs is 57° which leaves about 37% of the 7 Å sphere in reciprocal space unsampled. Fortunately, the amplitudes of the Fourier components in the missing regions are small. Thus, their 7 Å resolution map provides an accurate representation of the α -helical rods extending roughly perpendicular to the plane of the membrane, although the short connecting segments parallel to the surface are not yet seen. This remarkable three-dimensional picture illuminates both the objectives and the methods of structural biology.

In order to see inside protein molecules sharply at high resolution, Unwin and Henderson record very faint, out-of-focus micrographs of large periodic arrays at relatively low magnification. This "coincidence of contraries" reflects the antithesis of "distinct images and clear conceptions" recognised by S. T. Coleridge in a more epistemological context. The concepts for dealing with periodic images in real space have been most coherently formulated in reciprocal space in the 60 years since W. H. Bragg first pointed out the utility of Fourier synthesis for crystal structure analysis. Fourier transformation is not the only way to recover information about three-dimensional structure from electron micrographs but it has been, so far, the constructive way.

The development of Fourier microscopy of biological structures in Cambridge recapitulates in many ways the history of X-ray crystallography started there by W. L. Bragg in 1913 and, more particularly, protein crystallography begun there by J. D. Bernal and Dorothy Crowfoot Hodgkin in 1934. By the early 1950s Max Perutz and W. L. Bragg were mapping the outline of proteins by tracing the molecular transform and by using a kind of negative staining for X-ray diffraction; the internal structure of proteins became visible with X-rays in 1953 when Perutz successfully applied the isomorphous replacement method to solve the phase problem.

Electron micrographic crystallography was begun in the mid-1960s by Klug and his colleagues using optical diffraction and by 1968 it had become Fourier microscopy using computation of Fourier transforms of digitised images for the reconstruction of three-dimensional structures. There

is no "phase problem" in this microscopy since the phase information is contained in the image—but there was a "specimen problem" since the images, at best, showed little more than the shadow of the stain encasing the biological molecules. Unwin and Henderson have now introduced an ingenious but simple technique for solving the specimen problem which makes it possible to see inside molecules with electrons, perhaps to the ultimate limit of resolution of the microscope itself.

Any thin periodic structure with large ordered domains that can survive the extreme environment inside an electron microscope is a suitable object for imaging by this method. Their approach will be very useful for analysing the structure of molecules, such as lipids and some proteins, that form thin crystals difficult to study by X-ray diffraction. The unique power of the method for determining the structure of molecules that build cellular "surface crystals" is beautifully demon-

strated by Unwin and Henderson's image reconstruction of the purple membrane.

The purple membrane was isolated seven years ago in Walther Stoeckenius' laboratory as a pigmented by-product of studies on some other curious structures from this halophilic bacterium; it has now become an object of central importance in membrane biology. Photons absorbed by the chromophore, retinal, pump protons across this specialised membrane assembly. Analysis of the operation of this system is clarifying basic mechanisms in vision, photosynthesis and oxidative phosphorylation. Unwin and Henderson's image of the structure is comparably informative. The interlocking of the X-helical segments of the purple membrane protein, as in Crick's coiled-coil, and the fitting of the lipid bilayer in the interstices of the protein lattice illustrate key aspects of the structure of structural proteins and the organisation of membranes.

Towards universal geothermal power

from Peter J. Smith

"We are, with regard to this problem of utilizing the Earth's internal heat, very much in the position of an eighteenth century 'outcropper' quarrying for coal in the hillsides of Yorkshire. Noting the dip of the strata, he could quite well reason that far below the surface there must be immense reserves of coal, which on the one hand he did not need to exploit because the hillside quarry provided for all his immediate needs, and which on the other he could see no possibility of exploiting at a profit."

These words were spoken by John L. Hodgson at the British Association meeting in Leeds 48 years ago this week; but a similar statement could almost have been made today. The only difference is that the more generalised mid-20th century version of the 'hillside quarry'—cheap and abundant fossil fuel—is no longer with us. It disappeared so recently, however, that until now there has been little incentive to tap the "vast potentialities" of geothermal energy that Hodgson dreamt of.

Indeed, the whole subject of the Earth's internal heat has developed remarkably slowly from its origins in the 17th century. The earliest known reference to high temperatures within the Earth is that by Morin (*Nova Mundi Sublunaris Anatomia*, Paris, 1619) who found the air becoming warmer as he penetrated deeper into a

group of Hungarian mines. Some 50 years later Robert Boyle recorded (others') eyewitness accounts of temperature increases in mines and discussed the source and transport of underground heat, concluding that heat of chemical origin from the Earth's deep interior rises by conduction and the movement of material to produce the observed near-surface increase of temperature with depth.

From 1868 to 1883 a committee of the British Association pursued the subject vigorously and systematically and, having finally appreciated that the determination of heat flow requires the measurement of thermal conductivity as well as temperature gradient, obtained a mean heat flow of $1.3 \mu\text{calorie cm}^{-2} \text{s}^{-1}$, a value only slightly lower than today's average based on many more data.

But although 'academic' studies of heat flow are now beginning to contribute to the search for sources of geothermal power, the practical use of the Earth's internal heat (which has a much longer history) apparently proceeded quite independently, largely on the basis of chance discoveries of particularly conspicuous and high local concentrations of near-surface heat.

On the industrial front, the Italians have been extracting boric acid from natural steam jets at Larderello in Tuscany since the late 18th century. Historically, however, the Larderello

site is even more significant since it was there that geothermal power was first produced successfully (in 1904) when steam was piped to low pressure turbines driving small electrical generators. The dry (superheated) steam power stations at Larderello still account for about 40% of the world's geothermal power output, although there is now also a wet steam power station complex at Wairakei in New Zealand, a dry steam system at The Geysers in California and smaller stations in Japan, Iceland, Mexico and the USSR. The total geothermal power capacity installed throughout the world is now about 1,000 MW, which is still an insignificant proportion of the total power from all sources. In addition to power generation, however, geothermal steam is also used directly in various parts of the world for paper making, sewage treatment, potash mining, district space heating, growing greenhouse crops in cold climates and for many other purposes which can be effected close to the geothermal sources themselves.

The variety of uses for geothermal heat is impressive even without adding proposals in the pipeline. But as Morton C. Smith of the Los Alamos Scientific Laboratory pointed out last year at a meeting of the American Institute of Physics, the development of types of sources currently in use, especially for power generation, poses numerous as yet unresolved problems. For one thing, dry steam reservoirs such as those at Larderello and The Geysers seem to be extremely rare. There are fewer than a dozen known 'vapour dominated' geothermal fields of possible commercial size throughout the world, the largest of which would be capable of development to no more than 3,000 MW. It is possible, of course, that there are many dry steam sources which remain undiscovered because they have no surface indicators; but if so, the chances of finding them quickly are small because remote sensing systems capable of detecting subterranean steam are still poorly developed. Moreover, there are many scientific and technical unknowns. Is a dry steam reservoir a wasting or self-renewing asset? What are the interactions between heat flow, fluid flow, mass transport and tectonic stress changes? How can minerals (silica, for example) deposited from the steam be prevented from clogging up the works and volatiles (for example, hydrogen sulphide and boron and arsenic compounds) be prevented from causing pollution? Notwithstanding operating experience to date, none of these questions has been completely answered.

Natural geothermal systems in which the fluid is mainly hot water are much more common than those containing

predominantly dry steam; but the problems of power evaluation, development and production here are even greater, largely because of dissolved minerals. The natural pressures in most hydrothermal reservoirs are too low to maintain artesian flow, so the water must be pumped to the surface. But the hot brines rapidly destroy drilling equipment, borehole casings, pumps, valves and the rest of the hardware required to bring the fluid to the surface and extract heat from it. And once the heat is extracted the residual highly-concentrated brines then pose waste (thermal and chemical) disposal problems. The removal of large quantities of subsurface fluid can also lead to extensive subsidence. According to Smith, therefore, "the widespread exploitation of a large and readily available geothermal resource will evidently be delayed for some years until economic solutions to [these problems] have been demonstrated".

Where, then, does the long-term future of geothermal energy exploitation lie? The answer favoured by the Los Alamos group and currently being investigated by them is the extraction of heat from dry rock. Even in steam and water reservoirs well over half of the thermal energy resides in the rock, and rocks at depth are hot even when fluid is absent. In principle, therefore, it should be possible to extract geothermal heat anywhere in the world as long as sufficiently high temperatures are reached at depths to which drilling is economic.

Although it is seldom, if ever, acknowledged, the simplest way of achieving this dream was described in some detail by Hodgson in his talk in 1927 when he proposed an artificial version of the hydrothermal system that nature itself rarely provides. In other words, he suggested that cold water should be passed through the hot rock at depth and then recovered in the form of hot water or steam. This is almost exactly the method now adopted by the Los Alamos group with the difference that, whereas Hodgson envisaged a closed pipe circulation, the modern version has the injected water making direct physical contact with the hot rock and rising through a second borehole. An obvious unknown in either system, however, is whether there is an adequate area of contact at depth to achieve sufficient rock-to-water heat transfer. Hodgson's solution was to increase the length of his pipe at the bottom of the borehole if necessary; the modern idea is to fracture the rock at depth.

But whereas Hodgson's proposal was destined to remain unrealised, the Los Alamos suggestion is actually being put to the test at a site in New Mexico. According to Laughlin (*Geotimes*, 20,

March 1975), the main hole has already been drilled to a depth of 2,929 m in impermeable rock where the bottom-hole temperature is 196 °C. Hydraulic fracturing of the surrounding rock was successfully carried out at 1,981 m and will be repeated at the bottom. A second, somewhat shallower, hole is then to be drilled into the lower fracture zone to act as the hot fluid ascent route.

If the dry rock experiment in New Mexico proves scientifically and technically successful and an economically viable geothermal heat extraction system results, the way would clearly be open to a staggering increase in the use of this widely available and relatively pollution-free energy resource. Presumably it is still far too early to say when, or even whether, this ideal state will ever be reached. In the meantime, however, it must be evident that, other things being equal, both science and economics would benefit from application to areas where the heat flow is relatively high and the thermal energy is close to the surface.

The high heat flow anomaly in the Gulf of California, whose discovery is reported by Lawver *et al.* on page 23 of this issue of *Nature*, fulfils both of these criteria, having a remarkably high maximum value of 30 $\mu\text{calorie cm}^{-2} \text{ s}^{-1}$ (which compares with 4.5 $\mu\text{calorie cm}^{-2} \text{ s}^{-1}$ at the New Mexico site) and coming from a basaltic intrusion within 100 m of the surface. Admittedly the heat source is not continental; nor is it entirely clear to what extent, if any, hydrothermal fluids are involved. What is certain, however, is that Lawver and

his colleagues have discovered one of the Earth's major geothermal resources and that it is in just such areas that the real case for geothermal power will be fought. □

X-ray sources and the ionosphere

from L. J. C. Woolliscroft

THE lower ionosphere is a complex region of the upper atmosphere, with several ionisation mechanisms and high enough neutral species densities to cause many ion and electron reactions with the weakly ionised plasma. The production of ionisation by non-solar sources has been calculated by, for example, Velinov (*J. atmos. terr. Phys.*, **30**, 1891; 1968) for the influence of galactic cosmic radiation on the bottom of the D-region. More recently other non-solar objects have been invoked as sources of ionisation in certain conditions.

The propagation of low frequency (LF) and very low frequency (VLF) radio waves from extremely stable transmitters such as those used to broadcast atomic time allows the bottom of the ionosphere to be monitored continuously. Small changes in the phase and amplitude of the received LF and VLF signals from distant transmitters are used and some of these have been associated with the meridian transit of a strong X-ray source. Edwards *et al.* (*Nature*, **222**, 1053; 1969) found a nocturnal VLF effect from Scorpius XR-1 and the same source was found to give an effect at LF by Ananthakrishnan and Ramanathan (*Nature*, **223**, 488; 1969). Later positive results have included other celestial X-ray sources and also flare effects in Sco XR-1.

That these radio propagation effects are due to X-ray sources was challenged by Poppoff and Whitten (*Nature*, **224**, 1187; 1969) who showed that the ionisation production rate was at least an order of magnitude lower than that due to other mechanisms, especially that of Lyman α radiation ionising nitric oxide. A difficulty exists, however, in calculating the production of ionisation by Lyman α because the concentration of NO is somewhat uncertain.

A further complication comes from the masking effect of precipitating electrons producing ionisation at other than low latitudes which may account for some of the negative results such as those of Burgess and Jones (*Nature*, **224**, 680; 1969).

In this issue Karszenboum and Gagliardini (page 34) have calculated the production rate of ionisation due to several galactic X-ray sources using more recent spectra which extend to

A hundred years ago

PROFESSOR PALMIERI has discovered a new instrument which he calls a "diagometer," and which is constructed for the rapid examination of oils and textures by means of electricity. What the apparatus will do, Prof. Palmieri details thus:—1. It will show the quality of olive oil. 2. It will distinguish olive oil from seed oil. 3. It will indicate whether olive oil, although of the best appearance, has been mixed with seed oil. 4. It will show the quality of seed oils. 5. Finally, it will indicate the presence of cotton in silken or woollen textures. The professor has been complimented for this invention by the Chamber of Arts and Commerce at Naples, who have published a full description of the apparatus, with instructions for use.

from *Nature*, **12**, 427; September 9, 1875

higher energies and new data for the photoionisation yields. They compare their production rates for X-ray sources with the nocturnal production by other mechanisms and conclude that at least Sco XR-1 and probably some others could be significant at heights around 80 km.

The daytime production has to compete with solar X rays and ultraviolet, making measurements less easy. Ramanamurty *et al.* (*J. atmos. terr. Phys.*, **32**, 1721; 1970) found an amplitude variation over the LF path from Tashkent to Delhi at the time of an X-ray flare from Sco XR-1 and argued that this was theoretically possible under favourable geometry conditions with certain values for the NO concentration.

If the electron density of the D-region is enhanced by an X-ray source then the conductivity will also increase altering the pattern of ionospheric currents and thus the magnetic field. Murty and Yacob (*Planet. Space Sci.*, **22**, 1583; 1974) have studied the average sidereal time variation of the nocturnal geomagnetic horizontal component and found perturbations at the times of transit of some of the stronger X-ray sources. There is some doubt about their results since the magnitude of the perturbation does not correlate with the strength of the source as one would expect from a simple mechanism, indicating perhaps contributions from other effects.

The first daytime perturbation in the magnetic field is reported by Sastri and Murthy on page 35 of this issue, using magnetometer data during the same Sco XR-1 flare as Ramanamurty *et al.* Unfortunately a small solar X-ray flare occurred 33 min before the magnetic field perturbation, but Sastri and Murthy argue that this was both too weak and too early to cause the effect. The detailed mechanism for these geomagnetic effects remains uncertain but will probably involve a pattern of ionospheric current similar to that at the time of a solar flare.

The use of this ionospheric technique to study other astronomical sources such as γ -ray bursts is being studied by Mongain and Baird (paper A.2.7 presented at Cospar, Varna, June 1975). They argue that for the detection of γ bursts the ionospheric recombination time is very important and the best time may not be at night when the recombination time is short compared with the burst, but during the day. The analysis of their data is currently proceeding but they feel that as yet the work will tell us more about the ionosphere than about astronomy. The recently reported strong transient X-ray source A0621-00 discovered by the satellite Ariel V may also serve as a test for many of the theories. □

Primary, secondary, tertiary

from E. G. Richards

WHAT is the nature of the intercistronic regions in *Escherichia coli*? Platt and Yanofsky (*Proc. natn. Acad. Sci. U.S.A.*, **72**, 2399; 1975), have recently provided us with an answer in the case of the junction between the B and A cistrons of the *trp* operons. Making use of the high yield of the distal end of the corresponding messenger RNA from the *trp*ALD102 mutant and the fact that DNA from phage λ trpB27 and ϕ 80trpA37 carries sequences complementary to the end of the B and the start of the A cistron (and hence will hybridise with the messenger and protect it from nuclease attack in this region), they were able to isolate a fragment of 32 P-labelled RNA about 200 bases long. This was fingerprinted and a comparison of the oligonucleotides produced with the known sequence of the two proteins enabled them to determine most of the sequence. Any doubts about the part between the two translated regions were resolved by fingerprinting and sequencing the shorter polynucleotides produced by binding the longer piece to ribosomes to form the initiation complex of the A cistron and trimming the ends with nucleotides. The final result is of no little interest in that the termination signal for the B protein is found to be a single UGA codon which is out of phase with the AUG initiation triplet for the A protein; indeed, the final A of the termination codon is the initial A of the initiation codon, so that there are only two bases which are not translated. A consequence of this is that if the initiation recognition site of the A protein involves more than this UGAUG sequence it must also be translated as part of the B or A cistron. The authors point out that this and other known instances of dual function in mRNA provide some rationalisation for the degeneracy of the genetic code. They also note that close to the end of the B cistron and within the A cistron ribosomal binding site is a sequence GAGGGG which could bind to the CUCCUU sequence at the 5' end of the 16S rRNA; an interaction between such regions has been proposed by others.

Platt and Yanofsky do not speculate on possible secondary structures of their messenger fragment but such cogitations have been taken up by Pipas and McMahon (*Proc. natn. Acad. Sci. U.S.A.*, **72**, 2017; 1975) albeit for tRNA sequences rather than RNA. The consistency of the clover leaf structure with all known tRNA sequences as well as with recent X-ray

crystallographic investigations has probably convinced all but the most hardened sceptic of its reality. Nevertheless it is still valid to ask if the clover leaf structure is the structure with minimum free energy. Several authors have published descriptions of computer programs that will list all possible base pairing schemes compatible with a given sequence and other workers have provided, on the basis of work with model compounds, formulae for assessing the free energy of formation of secondary structures (from the random coil) in terms of contributions from various features such as loops, bulges and helical regions. Pipas and McMahon have put these two notions together and written a program that gives the free energy of all possible structures. They begin, as have others before them, by getting the computer to produce a list of all possible helical regions containing at least three base pairs. GU pairs are allowed but not at the end of a helical region; the hairpin loop must contain at least three bases and there are one or two other restrictions of a similar nature. The next step is to decide whether a given pair of helices are compatible or not, that is, whether they co-exist in the same structure. Clearly two helices that involve the same bases are incompatible and the authors also assume that if the bases in the hairpin loop of one helix participate in the formation of another helix, they only do so by pairing with other bases in this same loop. This latter restriction means that only structures resembling clover leaves are considered and more complicated patterns of folding (which cannot be drawn on a sheet of paper without the chain crossing itself) are not considered. This is probably the greatest weakness in their results but was required at the present state of play by the fact that the data for assessing the free energy of these more complicated structures are at present unknown. The next stage in the calculation was to enumerate one by one all the possible sets of compatible helices and then to work out the free energy of each.

Sixty-two tRNA sequences were presented to this program on a CDC6500 computer and all were analysed in less than 3 minutes. It was thus found that for 32 of these sequences, the clover leaf had the minimum free energy. Of the remainder, the minimum free energy structure of 13 corresponded to clover leaves with one or other (usually the DiHU) of the stems undone, and in five sequences the conventional acceptor stem contained non-standard base pairs which led to its elimination by the rules described above. This left 12 sequences which gave more extended structures as the most stable,

but their free energy was within 5 kcalorie of that of the clover leaf. Several explanations are available for the anomalies: the thermodynamic data on which the energy assessments are based may be faulty in some way or the native clover leaf form may be trapped in a metastable state; but the authors incline to the notion that tertiary interactions may tip the balance in favour of the clover leaf, and in the worst case only 5 kcalorie would be required.

The experimental elucidation of such tertiary interactions by NMR techniques is the subject of an interesting paper by Reid *et al.* (*Proc. natn. Acad. Sci. U.S.A.*, **72**, 2049; 1975). They determined the NMR spectrum of several highly purified species of tRNA in the -9 to -15 p.p.m. region. The -11 to -15 p.p.m. region gives a signal believed to emanate from the hydrogen-bonded ring NH protons and proportional to the number of Watson-Crick base pairs. Nevertheless it has been suspected that this low field region should contain resonances due to other sorts of base pair and to tertiary interactions. Their first interesting observation was that tRNA^{Val}, tRNA^{Arg} and tRNA^{Phe} all from *E. coli* gave a resonance corresponding to two protons at about -10.5 p.p.m., whereas tRNA^{Asp} from yeast gave a signal corresponding to about 10 protons in this region. The three *E. coli* sequences all indicate one GU base pair somewhere in their clover leaf structures while the yeast sequence indicates no less than three GU pairs and a GΨ pair as well. Since a GU pair involves two ring NH protons hydrogen bonded to oxygen atoms, the authors tentatively assign the -10.5 p.p.m. resonance to GU pairs.

The next point concerns a single proton resonance at -14.9 p.p.m. observed with these same three *E. coli* species but absent in several yeast tRNA spectra. For these *E. coli* species ring current shifts were not expected to result in any resonance below -14.5 p.p.m. Now the *E. coli* sequences all have s⁴U in position 8, whereas yeast tRNA^{Phe} has an unmodified U in this position which the X-ray diffraction data suggest is hydrogen bonded to A14. This suggested the attractive hypothesis that the -14.9 p.p.m. resonance corresponded to a S⁴U8-A14 base pair. This was neatly confirmed in the case of *E. coli* tRNA^{Val} by removing the sulphur by the action of cyanogen bromide. When this had been done, the tRNA was still active in aminoacylation (and hence presumably still had the native tertiary structure) but the -14.9 p.p.m. resonance had gone.

Other resonances in the -11 to -15 p.p.m. region probably remain to be

defined and assigned, because in the case of *E. coli* tRNA^{Val}, the integrated intensity from this region corresponds to 26±3 protons. One of these is, no doubt, the s⁴U-A tertiary interaction and 20 more no doubt correspond to the 20 Watson-Crick base pairs in the structure, but this leaves several more unaccounted for. The authors also suggest it likely that resonances corresponding to four protons in the -9 to -10 p.p.m. region in the case of *E. coli* tRNA^{Val} should be assigned to amino protons hydrogen bonded to ring nitrogens. Several such hydrogen bonds appear in the tertiary interactions discerned in yeast tRNA^{Phe} and *E. coli* tRNA^{Val} has corresponding bases in corresponding positions of the sequence.

Clearly more work needs to be done to confirm some of these tentative assignments and to elucidate others but this technique is reaching the point where it can provide information concerning the three dimensional structure of nucleic acids which is almost on a par with that obtained from X-ray crystallography. □

Ectoparasite provides cercarial model

from F. E. G. Cox

DIGENETIC flukes typically use two hosts during their life cycle, a mollusc and a vertebrate. The larval stage infective to the vertebrate is the cercaria which passes out from the snail and often has a short free-swimming existence before it gains access to its final host. Cercarial activity and infectivity have been studied in economically important species such as *Schistosoma mansoni* and *Fasciola hepatica* but it has been difficult to obtain much quantitative information from these studies because of problems such as having to dissect the final host to find out how many cercariae have actually established themselves. Because these problems are inherent in dealing with any internal parasite there has been no particular interest in developing alternative laboratory models and the study of the digeneans has therefore tended to suffer.

A convenient model is now available and it is an ectoparasite so easy to maintain that it will obviously become very important in the future. This fluke is *Transversotrema patialensis* and it lives under the scales of many freshwater fish including *Brachydanio rerio*, the Zebra Danio, which is sold

by many shops stocking tropical fish. The snail host is *Melanoides tuberculata* which is also available from aquarists. When infected fish are put in a tank containing uninfected snails the life cycle maintains itself indefinitely and the tank provides a convenient source of every stage required for experimental investigations. It is also easy to see how many adult flukes have become established simply by looking at the fish alive.

Transversotrema patialensis is therefore an ideal subject for the study of cercarial survival, activity and infectivity. Anderson and Whitfield (*Parasitology*, **70**, 295; 1975) have found that cercariae survive for a maximum of 44 h and that infectivity is restricted to half this time. As these cercariae do not feed they can live only as long as their energy reserves persist; Anderson and Whitfield have produced theoretical models relating infectivity to activity and activity to the amount of glycogen available and have found good correlations between their models and their experimental observations. They used electron microscopy as well as the more usual histochemical techniques in order to observe the depletion of glycogen in the cercariae.

Because the period of infectivity is so short the cercariae must locate, identify and attach to an appropriate host as quickly as possible. In the logical follow-up to the first study Whitfield, Anderson and Moloney (*Parasitology*, **70**, 311; 1975) were able to conclude that the location of the fish is a random process but that essential information regarding the suitability of the host is probably obtained by the use of receptors on the tail of the cercaria. Scanning and transmission electron microscope studies show that these receptors are unique but similar to types found in monogeneans, also ectoparasites, and which are thought to be concerned with chemoreception. After recognition of the host, attachment is accomplished first by means of adhesive pads, also on the tail, and then by the ventral sucker on the body after which the tail is lost and the fluke attains its final position under a scale.

These experiments open up a whole new field of investigation into the biology of flukes because the number of flukes that have actually established themselves can be counted without the need for killing and dissecting the host. These two papers are only a beginning but the standard set should ensure that further studies will also be based on critical experimental observations coupled with the use of techniques such as electron microscopy and mathematical analysis when necessary.

Solar oblateness

from David W. Hughes

THE Sun is thought to be flattened. Dicke and Goldenberg (*Astrophys. J. Suppl.*, **27**, 131; 1974) gave $(4.51 \pm 0.34) \times 10^{-5}$ as the value for this oblateness which means that the polar radius is 31.4 km smaller than the equatorial radius. Not much considering the mean solar radius is 695,997 km. Now it is clear that a rapidly rotating solar core with a period of between 0.5 and 2 d could provide an explanation for this flattening; but what is not clear is why the core should rotate so rapidly. This problem has been approached theoretically in a recent article by Schatten (*Astrophys. Space Sci.*, **34**, 467; 1975).

Obviously there must be some interaction between the quickly rotating core and the slowly rotating photosphere. Because the solar interior contains essentially all the mass and the angular momentum the photosphere would be spun up to the angular velocity of the interior unless there were some braking force acting on it. Dicke suggested that it is the accelerating torque exerted on the solar wind by the magnetic fields locked in the photosphere which provide this brake. In his first approach to the problem Schatten assumes that the rate of change of angular velocity with time is negligible and then finds that the angular velocity of the solar core is simply obtained by dividing the solar wind's torque, τ_{sw} , by the rate of change of the solar moment of inertia with time dI/dt . This moment of inertia varies because the nuclear reaction in which hydrogen is converted into helium reduces the number of ionised particles in the solar interior. To conserve the number of particles per unit volume and the pressure balance the core has to contract. Taking τ_{sw} as -8×10^{30} dyne cm, calculations of dI/dt as a function of r , the distance from the centre of the Sun, gives a rotation period of 17.5 h for $r < 117,000$ km and 25.4 $(r/R_{\odot})^2$ days for $r > 117,000$ km.

In Schatten's second approach the square of the angular velocity of the core is found to equal the mean power loss due to solar activity, P_{sa} , divided by $0.5 dI/dt$. As the core contracts the rotation power is liberated through the magnetic fields in sunspots. The energy lost in a solar cycle is calculated to be 10^{35} erg, equivalent to 2×10^{27} erg s^{-1} . However some of the spot energy might not get away from the Sun and Schatten, considering flares, gets a more dependable value of 10^{28} erg s^{-1} . These two values give a core rotation period of between 1 and 4 d. Third, the core rotation period must equal P_{sa}/τ_{sw} which gives periods of 0.5 to 5 d. These theoretical values of core

rotational velocity, based upon simple principles of conservation of angular momentum, energy and torque flow from the Sun, give a total oblateness of 3.4×10^{-5} for the photosphere which is in close agreement with the observed value of 4.5×10^{-5} .

Three interesting problems still remain. How does the solar core maintain its rapid rotation, bearing in mind that it is a highly conducting plasma? Also what effect does this oblateness have on celestial mechanics? The value obtained would produce a 4.05 s of arc per century advance in the perihelion of Mercury. This opens up the question of the accuracy of the general relativistic tensor theory of gravitation in comparison, say, with the scalar tensor theory. Third, can the rapid rotation of the core produce a lower central temperature in the Sun and thus help explain why the neutrino flux is less than expected?

It must be mentioned, however, that not everyone agrees with the oblateness values obtained by Dicke and Goldenberg. Hill and Stebbins in a paper scheduled for the September edition of *The Astrophysical Journal* discuss observations they have made at the University of Arizona's observatory in the Santa Catalina Mountains. The value they obtained for the oblateness is $(8.6 \pm 5.9) \times 10^{-6}$ which indicates that the Sun's shape is indistinguishable from that of a sphere. □

Nitrogen in synthetic diamond

from John Walker

DIAMONDS might be a girl's best friend, but in many respects they are very puzzling to scientists. One of the most intriguing problems concerns nitrogen, which is a very common impurity in diamond, and which has recently been studied in synthetic crystals by some Soviet scientists (Yu. A. Klyuev, V. I. Nepsha, and A. M. Naletov, *Sov. Phys. Solid State*, **16**, 2118; 1975). Nitrogen occurs in aggregated form in most natural diamonds, but in a few rare crystals the nitrogen atoms are isolated, each one replacing a single carbon atom. These crystals can be detected because the nitrogen is paramagnetic—it can be observed in magnetic resonance experiments.

Surprisingly enough, synthetic diamonds usually contain isolated paramagnetic nitrogen rather than clusters. To investigate this difference, and to check the earlier magnetic resonance work on natural diamond, Klyuev *et al.* have grown synthetic diamonds doped with the rare nitrogen isotope ^{15}N . This isotope has a nuclear spin of one-half, which gives rise to a magnetic

HLA histocompatibility system

In the article "Histocompatibility testing international" which appeared in the News and Views Section last week, the designation of the HLA system was changed during editing to HL-A. The WHO nomenclature committee mentioned in the report did in fact recommend that the whole region should now be designated HLA.

resonance spectrum somewhat different from the ^{14}N which predominates in natural diamond and has a spin of unity. The Russian workers were able to confirm the earlier work, allowing for the different nuclear spin.

Nitrogen in diamond can also be detected using infrared spectroscopy. The absorption spectra of the ^{15}N diamonds were very similar to those of ^{14}N crystals, except that a peak at $1,135 \text{ cm}^{-1}$ in the latter had shifted to $1,120 \text{ cm}^{-1}$. This was accounted for by the different masses of the two isotopes. A second peak, at $1,282 \text{ cm}^{-1}$, which can be caused by nitrogen clusters, was relatively strong in the doped crystals, irrespective of the isotope used. Undoped diamonds were also found to contain paramagnetic nitrogen, presumably as a result of contamination from the atmosphere, but had a relatively weak $1,282 \text{ cm}^{-1}$ peak. This suggests that nitrogen clusters are present as a minor species in doped synthetic crystals.

The most likely cause of this difference in nitrogen's behaviour in natural and synthetic diamonds is that different pressures and temperatures are used in the two crystallisation processes. Laboratory studies by the same authors (Yu. A. Klyuev, Yu. A. Dudenkov, and V. I. Nepsha, *Geo. chem. Int.*, **7**, 781; 1973) have shown that relatively high pressures and low temperatures during the synthesis process create cubic crystals which contain a lot of dispersed nitrogen, but few aggregates. Lower pressures and higher temperatures create octahedral crystals with a lot of nitrogen clusters, very similar to natural diamonds. What is not clear is whether the aggregates are formed directly during the crystallisation process, or whether they grow afterwards, in the high pressures and temperatures needed for synthesis. The authors favour the latter hypothesis, but further work is needed to decide the issue. The fact that synthetic diamond can now be doped with a specific isotope indicates how well the process can be controlled. This has implications not only for diamond physicists, but also in the realm of new applications. □

review article

Electrons in glass

Nevill Mott*

Our understanding of the behaviour of electrons in glasses, liquids and non-crystalline materials generally is decades behind the detailed theory available for crystals such as silicon and germanium. This article describes the advances made in the past fifteen years. It includes the work of the Leningrad school on amorphous semiconductors, the reason why they cannot usually be doped, the concept of "variable-range" hopping and the Cohen-Fritzsche-Ovshinsky and other models for the conduction band, and the reason why glass can be transparent. A crucial experiment, that of two-dimensional conduction in an inversion layer at a Si/SiO₂ interface, is described. Particular emphasis is given to concepts about which there is a disagreement and indeed controversy, such as the "mobility edge", the "minimum metallic conductivity" and the interpretation to be given to the ovonic threshold switch.

EXTRACTION of metals and the manufacturing of glass are two of our oldest technologies; metals are important because they are strong and ductile and glass because it is transparent. And yet it is remarkable that a serious attempt to understand the ductility of metals in terms of the movement of atoms came later than, for instance, the discovery of the neutron, though now it is fully achieved; on the other hand the transparency of glass and equally the properties of some glasses as semiconductors are still not properly understood, and cannot yet be calculated in the detailed way that the application of quantum mechanics has made possible for crystalline materials such as silicon. At the same time there has in the past few years been a surge of interest in the electrical properties of glasses and of non-crystalline—that is to say amorphous—materials generally; this article describes what has been happening, and why.

Interest arose from several sources. The photocopying process known as xerography makes use of photoconduction in amorphous selenium and led to very extensive work on that material in the Rochester Laboratories of the Xerox Corporation. The development by Ovshinsky and coworkers of an electronic switch based on thin glassy films of a mixture of selenium, tellurium, arsenic, germanium (STAG glasses) started a lively controversy which is not yet over. Work in Leningrad, Prague and Bucharest pioneered some aspects of the subject; in particular Kolomiets (for review see ref. 1) in the Ioffe Institute at Leningrad showed that the chalcogenide (that is, based on S, Se, Te) glasses, such as As₂Te₃ and the STAG glasses, behaved like intrinsic semiconductors and with a resistivity which, markedly unlike crystals, could not be much lowered by doping.

On the theoretical side the work of Ziman² showed that electrical conduction in one class of non-crystalline material, liquid metals, could be very simply understood. Also in 1958 P. W. Anderson's difficult paper³ on the absence of diffusion in certain random lattices, which he himself says is "often quoted but rarely read", introduced the idea of localisation: whereas an extra electron introduced into a crystal, with energy (in the jargon of the subject) "in the conduction band", can move quite freely but may be trapped by impurities, the mere absence of crystalline order can lead to a range of energies for which

an electron is trapped even in the absence of impurities. Anderson's paper proved controversial and—like many new ideas—took some ten years and many international conferences to establish itself.

With this introduction I shall return to the fact that glass is transparent. In crystalline materials our understanding of the difference between transparent non-metals and opaque metals goes back to the first application of quantum mechanics to solids by Bloch, Peierls and Wilson in the early 1930s. They treated electrons as freely moving, and described by wave functions with well defined wavelengths; for certain wavelengths Bragg reflection from the lattice takes place, leading to the well-known energy gaps and to the concept of full and empty bands for the allowed energies of the electrons. A transparent non-metal is a substance in which a full band is separated from an empty band by an "energy gap", with energy greater than the quantum of visible light. But this description depends essentially on the crystallinity of the material; there are no sharp Bragg reflections from glasses for electrons, any more than there are for X rays. In fact, when theorists round about 1968 first noticed that there was a problem here, one paper at an international conference was entitled "How can there be an amorphous semiconductor?" One could ask too "How can there be a transparent glass?", and this is part of the same question.

A first clue came from the discovery by Kolomiets¹ that, as already stated the low conductivity of the chalcogenide glasses is not increased even by very strong doping. The same is true of amorphous films of silicon which can be deposited by various methods. When the film recrystallises, but not before, the impurities will act as donors and will cause the conductivity to shoot up. The most likely explanation is the following⁴. In crystalline silicon, which has the diamond structure with each of the four valence electrons taken up in a covalent bond, an atom of phosphorus (with five electrons) is incorporated substitutionally, four electrons being used in bonds and the fifth being very weakly bound, so that at room temperature it is free to move and can contribute to a current. In a glass or in amorphous silicon, on the other hand, the structure will normally accommodate itself so that any atom has the right number of neighbours to accommodate all the electrons in bonds; phosphorus if pentavalent should have five, or if trivalent three. The absence of freely or loosely bound mobile electrons is why any

*Address: Cavendish Laboratory, Cambridge CB3 0HE, UK.

Fig. 1 Density of states $N(E)$ in an amorphous semiconductor plotted against energy. 1, Shows the form of $N(E)$ for the conduction band of a crystalline semiconductor; 2, the probable true form for the amorphous material; 3, the valence band and the dotted lines the "tails" as proposed by Cohen, Fritzsche and Ovshinsky. E_F is the Fermi energy and E_c the mobility edge. On the right the horizontal lines show energy levels in the traps (localised states), x denoting the position on space occupied by the traps. The line with the arrow shows a typical hopping process.

glass, is transparent. Colour in stained glasses is due to transition metal ions, where the inner electrons do not necessarily form covalent bonds and therefore are available for absorbing or scattering visible light.

A description of this kind is a long way from that usual among physicists for, say, crystalline SiO_2 or silicon, where all electrons are treated as free and the "energy gap" is a consequence of Bragg reflection. To treat the electrons as being stuck in bonds and to go no further seems a reversion to pre-quantum mechanical thought⁵. At present very active endeavours are in progress to bring a proper theoretical treatment to this model. In spite of a great deal of success, this work has not yet answered what is probably the most important question for glassy semiconductors, namely, what is the density of electronic states near the bottom of the conduction band? This is where electrons with thermal energies will be. For a crystal this density behaves like \sqrt{E} , where E is the energy; in a glass there should undoubtedly be a "tail", due to disorder, as suggested in Fig. 1. Those who feel that a gap is inconsistent with a non-crystalline structure have thought that the tail should extend an indefinite distance into the gap (the dotted line in Fig. 1) and should overlap a tail from the valence band; this was indeed proposed by Cohen, Fritzsche and Ovshinsky⁶ (the CFO model). But it now seems almost certain from observations that the "tails" are for all practical purposes limited; unless the glass has structural defects such as missing atoms, the band has a lower edge (E_A in Fig. 1). The states in the tail (shown shaded) are localised in the sense of Anderson; that is to say they consist of traps with a continuous range of energies. A sharp value of the energy E_c separating localised from non-localised states, is predicted and is known as the "mobility edge". Electrons with energies below E_c move from one localised state to another by the process known as "thermally activated hopping"—each time an electron moves it has to receive energy from lattice vibrations and its mobility tends to zero with the temperature; an

electron above E_c can move as in a crystal without help from lattice vibrations or thermal energy, though with a mean free path often as small as the interatomic distance.

Evidence for the existence of a mobility edge comes from experiments on the drift mobility of electrons injected into various materials, particularly experiments by Spear⁷ and coworkers on silicon glow-deposited from silane. These, unlike most evaporated or sputtered films, do seem to fall on microscopic voids, the presence of which makes the application of the theory for a continuous medium open to doubt. But perhaps another class of phenomenon gives a clearer demonstration of the concept. These are phenomena in which in a solid or liquid there is a degenerate gas or free electrons, so that the material behaves in all respects like a metal, but in which, as in a liquid metal, the positions of the atoms lead to a random electric field.

In liquid metals the random field leads to random scattering of the electrons, and as in Ziman's theory⁸ the scattering determines the mean free path. But—as is shown in Fig. 1, in the tail of a band the states are localised, and the electrical properties depend on whether the Fermi energy E_F , that is the energy of the highest occupied state, lies below E_c in the localised region, or above E_c . The conductivity of a metallic system depends only on the electrons with energies near the Fermi energy E_F , and so if E_F lies below E_c conduction is by hopping. I first showed that the conductivity as a function of temperature will then follow the law⁸

$$\sigma = A \exp(-B/T^{1/4}) \quad (1)$$

(where $T^{1/4}$ becomes $T^{1/3}$ in a two-dimensional system), a law which has been discussed extensively to find out in what conditions it should be valid. If on the other hand E_F lies above E_c , the conductivity tends to a finite value as the temperature tends to zero, which we can call metallic behaviour. If one then can vary the Fermi energy, for instance by varying the composition or the degree of disorder, or both, a kind of metal-insulator transition will occur, which has been named an "Anderson transition". The type of resistivity-temperature behaviour expected is shown in Fig. 2. When E_F lies below E_c , the conductivity σ at low temperature will follow the law (1); while at high temperatures current will be carried by electrons excited to E_c , so

$$\sigma = \sigma_{\min} \exp(-\varepsilon/kT), \quad \varepsilon = E_c - E_F$$

σ_{\min} , the lowest value of the conductivity for which there is no activation, is essentially that which one expects when the scattering is so strong that the mean free path becomes comparable

Fig. 2 Behaviour of the resistivity ρ of a substance in which there is a degenerate electron gas of which the Fermi energy can be shifted through the mobility edge. Disorder is increasing at E_F in the sequence numbered 1, 2, 3, 4.

with the distance between atoms (a). It is about $0.1e^2/\hbar a$, or in the neighbourhood of $1,000 \Omega^{-1} \text{ cm}^{-1}$. I have designated this quantity the "minimum metallic conductivity"⁹; the concept is not accepted by all theorists¹⁰ and there is a lively controversy at present on whether, as I believe, such a quantity exists.

There are many systems in which an Anderson transition can be observed, usually by using a series of specimens of varying composition or in heavily doped magnetic semiconductors by varying a magnetic field. But one of the neatest is the investigation due to Pepper^{11,12} and coworkers on conduction at the interface between n- or p-type silicon and a layer of silicon dioxide grown on the surface, using for instance the MOSFET (metal oxide silicon field effect transistor). In this device, by applying a voltage (the gate voltage) across the oxide layer, the number of electrons at the interface can be varied at will. Moreover these form a truly two-dimensional gas, and at helium temperatures the gas is degenerate. Also the oxide formed on the silicon contains positive and negative charges, distributed at random; therefore the electrostatic field seen by the electrons will vary in a random way, so that a "tail" is formed to the density of states, as in Fig. 1. By varying the gate voltage, therefore, and measuring the resistivity in the plane of the interface, it has proved possible to reproduce the behaviour of Fig. 2 in some detail. The experimental work, carried out in the Cavendish Laboratory in collaboration with Plessey Ltd, has two major achievements. Over four orders of magnitude the conductivity below 3 K has been found to be of the form

$$\sigma = A \exp(-B/T^n) \quad (2)$$

with $n = 0.32 \pm 0.02$, a measurement which established the two-dimensional nature of the phenomenon, which in all respects follows the predicted behaviour of Fig. 2; and secondly the minimum metallic conductivity can be established experimentally.

For a two-dimensional system the calculated value is about $0.1e^2/\hbar$, and it has been suggested by Thouless (unpublished) that this is a universal constant, not depending on the form of disorder; in conventional units this is about $10^{-5} \Omega^{-1}$.

The metal-insulator transition shown in Fig. 2 is essentially due to disorder and is quite different from the "Mott transition"^{13,14} which is first order and a consequence of interaction between electrons.

Conductivity having the forms (1) and (2) is known as variable-range hopping. It arises because the probability that an electron jumps from one localised state to another at a distance R is of the form.

$$C \exp(-2\alpha R - (W/kT)) \quad (3)$$

where W is the energy difference between them and α is a constant. The greater R the greater the choice of state, so if the electron chooses the smallest available value of W ,

$$W \propto [1/(4\pi/3)] R^3 N(E_F)$$

Equation (1) comes from choosing R to maximise the quantity in equation (3). In two dimensions πR^2 replaces $(4\pi/3)R^3$, so equation (2) follows. Variable-range hopping has been extensively observed, but deviations from equation (1) occur in many cases, probably because the assumption made that C and $N(E)$ are sufficiently independent of energy and temperature may not be valid.

Experiments such as that described above give us a lot of confidence in the concept of a mobility edge in the conduction band of any disordered system, and in the possibility of applying it to real glassy materials, and indeed there is a multitude of papers in which this is done (see for instance ref. 13). One of the difficulties many theorists had in accepting Anderson's localisation idea, together with a continuous distribution of trap energies, was the intuitive feeling that an electron in a trap, if it tunnelled far enough, would find another trap with exactly the

Fig. 3 Current-voltage curve for an ovonic threshold switch in on- and off-states.

same energy, and so the conductivity could not be temperature-activated and should not tend to zero at low temperatures. The reason why this is not so is rather subtle⁴; the experimental evidence from results such as those of Fig. 2 is, however, overwhelming. Also the measurements by Spear and coworkers⁷ of the drift mobility of injected electrons, that is to say the rate, at which they drift across a specimen under the influence of an electric field, gives very firm evidence; at low temperatures the electron hops from one localised trap to another, at high temperatures it is excited to the mobility edge. But in many materials, particularly chalcogenides the drift mobility seems to depend on structural defects, and indeed we have little idea of their nature or whether it is even in principle possible to have a fully coordinated glass without them.

I feel that some of the most important developments in this field are likely to concern the kinds of structural defects in glasses, their effect on photoconduction and their relation to recombination centres in crystals. Even in crystals the mechanism ("multiphonon transitions") by which electrons and holes recombine without emission of radiation is imperfectly understood, in spite of much theoretical work; in silica glasses, we have very little idea. A challenging and controversial paper by Anderson¹⁴ may be relevant here, concerned with the way in which an electron in a trap deforms its surroundings. Also amorphous silica in silicon technology and amorphous tantalum oxide in anodic capacitors present a host of problems.

There is another problem which obstinately defies complete understanding, namely the mode of action of the threshold switch developed by S. R. Ovshinsky¹⁵ in his firm Energy Conversion Devices. In its simplest form this consists of a layer of STAG glass about $1 \mu\text{m}$ thick between two molybdenum electrodes. Figure 3 shows schematically how the switch behaves. In the off-state the material is a semiconductor with highly temperature-dependent impedance; in the on-state, which can be maintained as long as the current does not fall below M (the minimum holding current), the current is quite insensitive to temperature. It can reach more than 10 mA, probably in a channel a few μm thick. The controversy is about whether the on-state is due to a thermal instability, a hot channel at perhaps 500°C being formed¹⁶, or whether the channel is merely warm and electrons and holes are injected from the two electrodes¹⁷. A measurement of the temperature of the conduction channel would resolve the problem, but this has not proved possible; the radiation from a switch in the on-state has, however, been observed^{18,19} and bears no resemblance to black body radiation.

The controversy has been heated and at times bad-tempered, because the threshold switch was presented with commercial claims as something new, and some scientists in other industrial

laboratories claimed that it was a thermal instability and they had known about it for a long time. In spite of the many successes of the thermal theory I believe, though without absolute certainty, that there is indeed something new here, for which Ovshinsky and his many collaborators in American universities deserve credit. If electrons and holes are injected, degenerate gases of electrons and holes must be formed and the Fermi energies of one or other of them must lie above the corresponding mobility edge; otherwise the large observed currents with no thermal activation could not occur.

Indeed, just as this article is going to press, a good deal of new evidence is appearing in favour of an electronic and against a thermal model (ref. 20 and E. Peterson, G. W. Lake and D. Adler, unpublished).

How specific are nuclear “receptors” for thyroid hormones?

J. R. Tata

National Institute for Medical Research, Mill Hill, London NW7 1AA, UK

The presence of “high-affinity-saturable” binding sites for thyroid hormones of similar characteristics not only in isolated nuclei but in all the major extranuclear cellular components, as well as the failure of cytosol to promote nuclear binding, invalidates the analogy with steroid hormone receptors and necessitates a more critical assessment of the physiological relevance of current approaches to binding of thyroid hormone in vitro to nuclear preparations.

THE identification of specific hormone-binding components or “receptors” in target cells is considered to be a primary requirement for an understanding of hormone action. It is now commonly held that polypeptide hormones exert their action by interacting with binding components on the surface of the cell¹, whereas some, but not all, small molecular weight hormones act through intracellular receptors². The latter generalisation is based largely on the concept of a two-step process of steroid hormone action whereby the hormone would first interact with a cytoplasmic receptor after which the hormone-receptor complex would be transferred into the nucleus where the complex or the hormone alone would initiate its physiological action^{2–6}. Since steroid^{2,5–8} and thyroid hormones^{9,10}, in common with other growth and developmental hormones^{11,12}, markedly stimulate nuclear transcriptional activity, the concept of a nuclear site of specific hormone receptor(s) has recently been extended to thyroid hormones^{13–23}.

Early studies with cellular extracts revealed that both the “soluble” cytoplasmic fraction (“cytosol”) and various particulate subcellular fractions (mitochondria, microsomes, nuclei, debris, and so on) were equally effective in binding radioactive thyroid hormones *in vivo* or *in vitro*^{24–28}. These

studies were performed with hormones of low specific radioactivity so that they could have only indicated nonspecific binding sites and not detected the easily saturable and physiologically more relevant binding sites or “receptors”. Recent studies on nuclear location of thyroid hormone receptors have been based on the use of ¹²⁵I-labelled tri-iodothyronine (T₃) of high specific radioactivity and these suggest that a rat liver nucleus has about 5 × 10³–10 × 10³ “specific” sites for this hormone^{15,17,18,20}. Before these sites can be considered physiologically significant, however, it is essential to demonstrate that other subcellular components do not comprise sites of similar T₃-binding characteristics. In view of the importance of this question it may seem surprising that no studies have so far examined, in identical conditions, the thyroid hormone-binding characteristics of the major subcellular fractions derived from the same tissue, although the cytosol fraction is known to account for a large fraction of both high and low affinity sites in different tissues^{24–32}.

I shall describe here experiments which show that the binding of highly radioactive T₃ *in vitro*, as used in other recent studies, is not restricted to the nucleus or nuclear extracts, but that preparations of cytosol, plasma membrane, microsomes and inner mitochondrial membranes all exhibit similar “high-affinity” binding characteristics. The studies described below only deal with rat liver for the sake of comparison since most recent work on nuclear receptors is restricted to this tissue. All subcellular preparations exhibited two major classes of T₃-binding sites: (1) those with high affinity and relatively low capacity (commonly termed “specific”), and (2) those with low affinity and virtually non-saturable (“nonspecific”). This paper also describes a direct method for determining free and bound thyroid hormone on DEAE-cellulose filter disks, adapted from a procedure described earlier for glucocorticoids³³.

Characteristics of binding

Adsorption of the ^{125}I - T_3 -protein complex on DEAE-cellulose gave a linear binding response for both particulate and soluble cellular components (Fig. 1). That the fraction of radioactivity retained on DEAE-cellulose filters represents T_3 bound to macromolecules was confirmed by precipitation and washing with trichloroacetic acid of identical samples. By treating the solution of radioactive T_3 with DEAE-cellulose just before use, the fraction of ^{125}I retained on "blanks" was reduced to below 4%. Any ^{125}I -iodide would thus be retained by the filters but not free T_3 or iodothyronine analogues. A major advantage of this procedure over those commonly in use is that the radioactivity measured on the adsorbent is a direct measure of the T_3 bound to protein or nucleic acids, whether the latter are in solution or not, and, therefore, more accurate than indirect methods involving the introduction of an

Fig. 1 Binding of ^{125}I -tri-iodo-L-thyronine (Abbott Laboratories, specific activity 322 Ci mmol^{-1}) to increasing amounts of nuclei and cytosol from livers of normal and thyroidectomised rats (150 g, Carworth Europe). Nuclei were freshly prepared from three livers by the method of Blobel and Potter³⁴, except that the homogenising medium was 0.25 M sucrose, 50 mM Tris-HCl (pH 7.6) 12.5 mM NaCl, 12.5 mM KCl and 5 mM MgCl_2 (STKNaM) and the nuclear pellet suspended in the same medium at a concentration of 4–6 mg DNA ml^{-1} . Cytosol was prepared from rat liver, perfused with 100 ml of Krebs-Ringer phosphate buffer, washed and homogenised in 2 vol of STKNaM. After two centrifugations at 10,000g for 20 min, the mitochondria-free supernatant was centrifuged at 105,000g for 3.5 h. The resulting supernatant, termed "cytosol", was stored at -30°C in small aliquots until use. Because of hormone adsorption problems, contact with glassware was avoided for all binding studies which were carried out in polycarbonate tubes, while all volumetric measurements were performed with polypropylene pipettes and syringes. Tissue preparations were incubated for 10 min at 37°C in a total volume of 260 μl made up with STKNaM. ^{125}I - T_3 was diluted with STKNaM to reduce the propylene glycol concentration down to below 5%. In this experiment, all samples were incubated with ^{125}I - T_3 at a final concentration of 2.5×10^{-10} M (43,000 c.p.m.). In this and all other experiments, the diluted ^{125}I - T_3 solutions were passed through three layers of DEAE-cellulose filter disks (Whatman DE 81), presoaked in STKNaM, through a Millipore plastic Swinney adaptor attached to a 1-ml syringe just before incubation. This procedure removed ^{125}I -iodide and ensured low blanks. At the end of the incubation, the contents of the tube were immediately deposited on two layers of DEAE-cellulose disks, presoaked in 20 mM Tris (pH 7.6) and 1.5 mM EDTA held in a Millipore filter manifold. The vacuum was adjusted so that filtration took 10–20 s only and the contents of the tubes and filters were rinsed 5–7 times with 1 ml of Tris-EDTA solution. The filters, before they were dried, were crushed into polycarbonate tubes and ^{125}I determined in a Packard Auto-gamma counter. In all experiments, protein-free controls were processed simultaneously and corrections were made for blanks which were usually of the order of 2–4% of the total input radioactivity. Protein, RNA and DNA were measured by standard procedures^{35–38}. Each value is the mean of four determinations on two parallel incubations. The average variability was $\pm 6\%$. \circ , Nuclei; Δ , cytosol; — — —, normal; — — —, thyroidectomised.

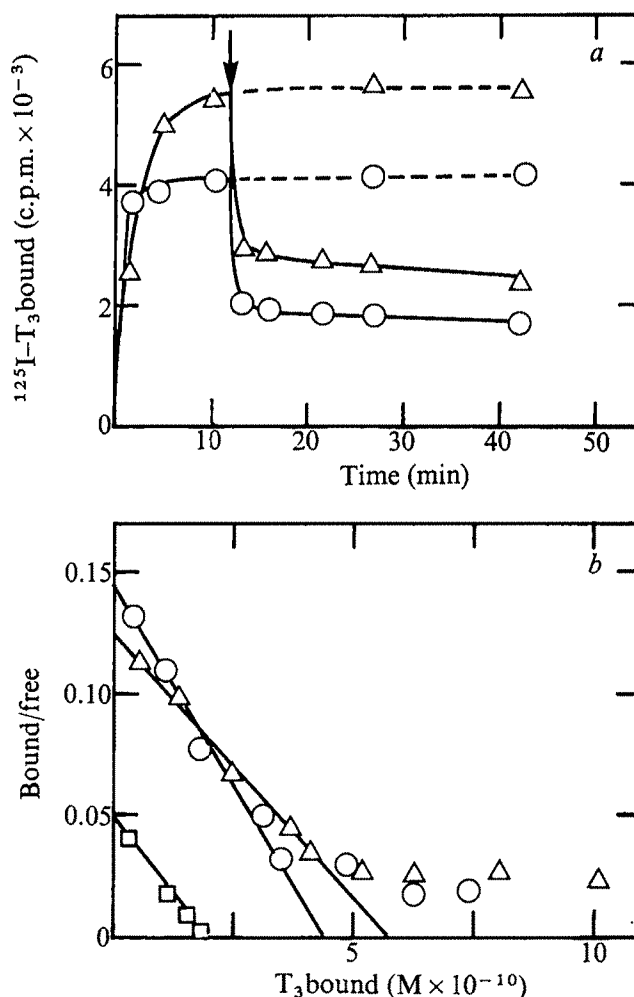

Fig. 2 T_3 -binding characteristics of nuclei, nuclear sap and cytosol from thyroidectomised rat liver. Nuclei and cytosol were prepared as described in Fig. 1 and nuclear sap as described in legend to Table 2. *a*, Time course and reversibility of binding. Cytosol (1.1 mg protein) and nuclei (190 μg protein) were incubated with 100 μg of ^{125}I - T_3 (36,000 c.p.m.) at 37°C for different periods of time. To one set of tubes, 6 μg of non-radioactive T_3 were added at 12 min (indicated by the arrow) and the incubation continued for a further 30 min. To the other set no "cold" T_3 was added. The radioactive T_3 bound to cytosol or nuclei was determined as in Fig. 1. \circ , Nuclei; Δ , cytosol; \square , nuclear sap. *b*, Scatchard plot analysis of affinity and capacity of binding of ^{125}I - T_3 to nuclei, cytosol, and nuclear sap. Different amounts of T_3 , containing a fixed amount of ^{125}I - T_3 (35,000 c.p.m.) were incubated with nuclei (175 μg protein), nuclear sap (45 μg protein) and cytosol (236 μg protein) for 10 min at 2°C . The other procedures are as described in Fig. 1. \circ , Nuclei; Δ , cytosol; \square , nuclear sap.

insoluble "binder" of free hormone, such as dextran-coated charcoal.

All the physicochemical measurements in this work were made in parallel in normal and thyroidectomised animals since nearly half the liver nuclear T_3 -binding sites measured in thyroidectomised rats are occupied by endogenous thyroid hormone in normal animals^{17,20,38}. The binding of ^{125}I - T_3 at low concentrations (2×10^{-10} – 5×10^{-10} M) was very rapid ($T_{1/2}$ of 1–3 min) for both nuclei and cytosol alone (Fig. 2*a*). Displacement of radioactive hormone bound to these fractions by the addition of a large excess of unlabelled T_3 gave, at equilibrium, an approximate dissociation half time of 70 min for cytosol and 36 min for nuclei. ^{125}I - T_3 was also similarly displaced by higher concentrations of L-thyroxine and other iodothyronine analogues (not shown in Fig. 2*a*). When the binding of T_3 was measured at different hormone concentrations, it was found that for all cellular components from thyroidectomised liver, there exist at least two major classes of

Fig. 3 Competition between cytosol and nuclei for the binding of $^{125}\text{I-T}_3$ at low and high concentrations of the hormone. A fixed amount of nuclei (180 μg protein) were incubated with different amounts of cytosol at 37°C for 10 min with either $4 \times 10^{-10}\text{ M}$ (17,000 c.p.m.) or $2 \times 10^{-7}\text{ M}$ (25,000 c.p.m.) $^{125}\text{I-T}_3$. At the end of the incubation, the nuclei were separated from the cytosol by centrifugation at $2,000g$ for 5 min and the bound radioactivity determined in each component by adsorption to DEAE-cellulose disks. Values for "O" cell sap are from incubations carried out in the absence of cell sap and therefore represent bound $^{125}\text{I-T}_3$ in the nuclear supernatant. Other conditions as in Fig. 1. \circ , Nuclei; \triangle , cell sap; —, $4 \times 10^{-10}\text{ M T}_3$; ---, $4 \times 10^{-7}\text{ M T}_3$.

binding sites: those that have high affinity and low capacity and those that exhibit a 100-fold lower binding affinity but are difficult to saturate. Data, such as those presented as Scatchard plots in Fig. 2b, gave values for association constant (K_a) of $1.2 \pm 0.3 \times 10^8\text{ M}^{-1}$ and $0.8 \pm 0.3 \times 10^8\text{ M}^{-1}$ for nuclei and cytosol respectively. The binding capacity for the same two fractions was $3.0 \pm 0.9\text{ pmol}$ and $0.7 \pm 0.2\text{ pmol}$ per mg protein, respectively. These values are within the same range as those reported elsewhere for nuclei^{15,17,18,20} and cytosol²⁸⁻³⁰ *in vitro*, especially when one takes into account the quite different methods used for studying binding.

Nucleus and cytosol

An outstanding characteristic of intracellular translocation of steroid hormones is the process by which the hormone has to be complexed to cytosol receptors before it can move into the nucleus. The receptor in the cytosol is different from the "acceptor" sites in the nucleus and the translocation of the hormone from one subcellular site to the other requires a temperature-sensitive activation step^{2-8,39}. In order to test the validity of a steroid hormone analogy for thyroid hormone

receptors, it was reasoned that if the same principle governed the two classes of hormones, then coincubating $^{125}\text{I-T}_3$ with nuclei in the presence of cytosol should enhance in a cooperative fashion the concentration of the hormone in the nucleus. On the other hand, an independent interaction between the hormone and the two subcellular fractions should lead to a competition between the subcellular components.

Figure 3 shows that the addition of increasing amounts of cytosol to nuclei led to a corresponding decrease in the radioactivity recovered with the nuclei. When one takes into account the binding constants and capacities given in Fig. 2b (see also Table 2) for the two fractions, the results can be accounted for by competition by the two subcellular fractions for the available T_3 , governed by simple mass action kinetics. Similar results were obtained at both low ($4 \times 10^{-10}\text{ M}$) and high ($2 \times 10^{-7}\text{ M}$) concentrations of the hormone, that is at concentrations above and below saturation of binding sites of high affinity and limited capacity. The results in Fig. 3 were obtained at 37°C so that a cytosol receptor activation step, analogous to that involving steroid hormones, should have given the opposite result. From Table 1 it is clear that preincubating cytosol at 37°C failed to enhance the uptake of the hormone into nuclei at either 2 or 37°C . Many permutations, to be reported elsewhere, of coincubating nuclei and cytosol at different temperatures also failed to reveal a temperature-dependent activation step for a cytosol-nuclear transfer mechanism. Although they did not specifically look for a thermosensitive activation step, Surks *et al.*¹⁷ and De Groot and Torresani¹⁸ also concluded that the cytosol did not play a role in the transfer of the hormone to the nucleus. The steroid hormone analogy for early events in hormone action is clearly not applicable to thyroid hormones.

Other cellular components

The above findings of not too dissimilar classes of competing binding sites in the nucleus and soluble cytoplasm raised the question of their specificity with respect to other cellular components. An examination of all the major subcellular and subnuclear fractions was undertaken in which the physicochemical characteristics for $^{125}\text{I-T}_3$ binding were measured simultaneously and under identical conditions. Very rigorous conditions were established in the preparation of subcellular fractions to eliminate mutual contamination. Thus, a subfraction of plasma membranes comprising only the outer face of the cell surface⁴¹ was used in order to exclude microsomal contamination. Since the outer membrane of mitochondria shares some common components with the endoplasmic reticulum⁴², a preparation of only the inner mitochondrial membrane⁴³ was used. Similarly, nuclei were washed with an amount of detergent (0.2% Triton) known to remove both the outer and inner nuclear membranes⁴⁴, again in order to eliminate microsomal contamination. Recently, many reports have indicated that the nuclear site for thyroid hormone binding is in the chromatin from which it can be extracted with 0.4 M KCl ^{14,17,20-22}. Such treatment of chromatin is known to extract the bulk of non-histone acidic nuclear proteins⁴⁵ as well as acceptor sites for oestrogen, progesterone, androgen and corticosteroids in their respective target nuclei^{2,4}.

Table 1 Absence of temperature-dependent activation step for transfer of bound $^{125}\text{I-T}_3$ from cytosol to nuclei

Temperature of preincubation of cytosol + $^{125}\text{I-T}_3$ ($^\circ\text{C}$)	Temperature of incubation of cytosol + nuclei ($^\circ\text{C}$)	Bound $^{125}\text{I-T}_3$ (c.p.m.) recovered in	
		Nuclei	Cytosol
2	2	1,923	2,422
2	37	1,793	2,479
37	2	2,026	1,941
37	37	1,701	2,294

Cytosol from thyroidectomised rat liver (1 mg protein in 0.16 ml of STKNaM) was preincubated with $2 \times 10^{-10}\text{ M }^{125}\text{I-T}_3$ (35,000 c.p.m.) for 10 min at either 2 or 37°C and then chilled in ice for 5 min. 0.1 ml of a freshly prepared nuclear suspension (275 μg protein) was then added and the mixture incubated for 10 min at 2 or 37°C after which nuclei and cytosol were separated as indicated in Fig. 3. The fraction of $^{125}\text{I-T}_3$ bound was determined as described in Fig. 1.

Table 2 Characteristics of binding of ^{125}I -tri-iodothyronine to nuclear and extranuclear components

Component	Rat	Association constant K_a (M^{-1})	No. of binding sites M (pmol per mg protein)	$T_{1/2}$ (min) for Association	$T_{1/2}$ (min) for Dissociation
Nuclei	Normal	2.4×10^8	1.73		
	Thyrex	1.3×10^8	2.96	2.9	36
Cytosol	Normal	8.0×10^7	0.67		
	Thyrex	2.3×10^8	0.69	3.0	70
Nuclear sap	Thyrex	1.7×10^8	2.10	5.9	
0.4 M KCl Extract of chromatin	Thyrex	9.3×10^7 *	0.15	8.5	
Inner mitochondrial membranes	Normal	7.3×10^7	0.27	7.5	20
Plasma membranes	Normal	8.2×10^8	0.32		
Microsomes	Thyrex	5.9×10^8	0.08	8.0	80

Nuclei and cytosol were prepared as described in Fig. 1. Nuclear sap was prepared by gentle sonication of nuclei according to the method of Tata and Baker⁴⁶. The chromatin pellet remaining after removal of nuclear sap was extracted twice at 2 °C with 0.4 M KCl (chromatin from 3 g equivalent liver ml^{-1}) and both the 0.4 M KCl extract and nuclear sap were dialysed overnight against three changes of 200 vol of STKNaM. Much of the protein in 0.4 M KCl extract precipitated out during dialysis and it was redissolved in 0.4 M KCl. Both the nuclear sap and the salt extract of chromatin were concentrated in an Amicon (Minicon B15) dialysis concentrator to a protein concentration of 1–2 mg ml^{-1} . Plasma membranes were subfractionated to yield the outer face components according to Wisher and Evans⁴¹ and the inner mitochondrial membranes prepared by the method of Greenawalt⁴². Microsomes were the pellet obtained from the preparation used for obtaining cytosol. The binding characteristics were calculated according to the details given under Figs 1 and 2, except that the standard temperature was 37 °C. Nuclei, when not fractionated, were washed once with 0.2% Triton X-100 followed by two washes with STKNaM. Thyrex: thyroidectomised.

*The values for 0.4 M KCl extract of chromatin are rough estimates only because of the problem of protein precipitation in STKNaM.

Similar preparations were, therefore, also made from rat liver chromatin but after previous removal of "nuclear sap" which contains soluble nuclear proteins released by gently disrupting nuclei at isotonic salt concentration⁴⁶. Since some subcellular components of liver degrade thyroid hormone²⁸, comparison of thyroid hormone binding to different subcellular fractions was carried out both at 37 and 2 °C.

The results, summarised in Table 2, show that all subcellular fractions exhibited the presence of apparently "specific" and readily saturable T_3 -binding sites. Their relative affinities varied only over a range of ± 5 -fold, which is not considerable when considering that one is comparing binding of a ligand to macromolecules in solution for some components and in a suspension of membranes or complex macromolecular particles in others. The number of T_3 -binding sites per nucleus was of the order of 10,000 but the total binding capacity as expressed per mg protein or per g equivalent of tissue varied over a wide range for the different fractions. As regards fractionation of nuclei, in results to be presented elsewhere (J.R.T., K.M.B.S., and B.B., unpublished observations), more than half the ^{125}I - T_3 bound to nuclei was recovered in the euchromatin fraction. This is in agreement with recent reports from Baxter's laboratory^{23,40} but whether or not the endogenous hormone is directly bound to DNA as concluded by these workers or to non-histone protein in intact chromatin, as proposed by others^{14,15,20–22}, is difficult to decide. In our hands much difficulty was experienced in studying the binding under standard ionic conditions to the non-histone proteins extracted from chromatin by 0.4 M KCl because of precipitation of protein on lowering the salt concentration. On the other hand, the nuclear sap fraction, which represents soluble nuclear proteins released on gentle sonication of nuclei at relatively low salt concentrations⁴⁶, had T_3 -binding sites present at higher concentration (as expressed per mg protein) than in total euchromatin (J.R.T., *et al.*, unpublished). These findings (Table 2) of the ubiquitous distribution of T_3 -binding sites in nuclear and extranuclear fractions of rat liver are compared in Table 3 with the characteristics described by other workers for this and other tissues, thus establishing that such sites are certainly not restricted to the nucleus.

Hormone binding and action

The above results raise several questions concerning the relevance of binding of thyroid hormone to subcellular components *in vitro* to the initiation of the physiological actions of the hormone. First, do the T_3 -binding component(s) of K_a of 10^8 – 10^9 M^{-1} in the different subcellular fractions represent the same or different molecular species? An electrophoretic

or sedimentation analysis of the solubilised binding components of cytosol and nuclear sap would provide a partial clue. Whatever the answer, it seems that the emphasis given in recent work to nuclear binding of T_3 *in vitro* to explain thyroid hormone action is unjustified nor is the steroid hormone analogy valid. Second, the quantitative aspects of the binding raise some doubts about the relevance to physiological action. Except for the pituitary³⁸, only about 15–20% of the endogenous or exogenous hormone is associated with the nuclei from liver or kidney homogenates^{16,21,38}. The "specific" high-affinity binding of T_3 to various subcellular fractions reported here and elsewhere^{13–23,27–32,38} is not much different from that described in our earlier studies^{27,28} with hormone of low specific radioactivity binding mostly to the low-affinity, non-saturable sites. Moreover, both the high-affinity and low-affinity sites in the nucleus and elsewhere do not exhibit a stringent specificity with respect to the biological activity of thyroid hormone analogues. In fact, the relative affinities of various analogues reported for the easily saturable, high-affinity sites^{18,21,30,31} are very similar to those reported some years ago for the low-affinity, "nonspecific" sites^{27,28}. On the other hand, a high degree of correlation between physiological potency or anti-hormone activity has been a major argument in supporting the physiological relevance of nuclear binding of steroid hormones^{2,4,6–8,47,48}. The figure of 5–10,000 binding sites for T_3 per rat liver nucleus may also be too high if one considers the phenomenon in terms of specific induction of proteins through genetic activation. The affinity of the nucleus for tri-iodothyronine is not much greater than that exhibited by cytoplasmic fractions or of plasma thyroxine-binding globulin (TBG) for either tri-iodothyronine or thyroxine ($K_a = 2.0 \times 10^9 \text{ M}^{-1}$ and $2.4 \times 10^{10} \text{ M}^{-1}$, respectively)²⁸. Oppenheimer *et al.*¹⁶ calculated the affinity of the rat liver nucleus for T_3 *in vivo* as K_a of $4.7 \times 10^{11} \text{ M}^{-1}$, a value nearly 1,000 times higher than that reported from the same laboratory⁴⁷ for the "specific" interaction *in vitro*. Interestingly, intact lymphocytes bind T_3 with a K_a of $9.4 \times 10^{11} \text{ M}^{-1}$ (binding capacity = 6.5×10^{-4} pmol per 10^7 cells) but the location of the binding sites has not been described⁵⁰. The discrepancy between the relative affinities of nuclei *in vivo* and *in vitro* has been explained on the basis of the deleterious effects of ionic and other conditions *in vitro*¹⁷ but then the same argument should also apply to extranuclear fractions. There is, in fact, no direct evidence that the binding to nuclei *in vitro* tells us much about the properties of a possible true nuclear receptor for thyroid hormone that may be present in much lower concentration. Similar questions have been raised for extremely high-affinity nuclear binding for oestradiol present in amounts as low as

Table 3 Characteristics of binding of ^{125}I -tri-iodothyronine to "specific" high affinity sites in nuclear and cytosol preparations described by other workers

Preparation	K_a (M^{-1})	No. of sites	$T_{1/2}$ (min) for		Ref.

*NHP, Non-histone protein (nuclear proteins soluble in 0.4 M NaCl).

10–1,000 molecules per cell in the uterus^{6,51,52}. It is hard to visualise how physiologically important receptor molecules could be detected at that level for thyroid hormones by binding techniques currently available.

High-affinity steroid-binding sites have also been recently detected in extranuclear sites (plasma membranes, microsomes) in tissues where similar nuclear binding sites have been well characterised^{53–55}. An ubiquitous distribution of not only thyroid but also steroid hormone-binding sites leads to a consideration of possible multiple sites of initiation of actions of growth and developmental hormones. It is well known that multiple^{9–11,56} or "pleiotypic"⁵⁷ responses are elicited by all growth and developmental stimuli, whether they be hormonal or not, before induction of new protein or messenger RNA species. Many of these effects, such as the alteration of cell surface, permeability towards small molecules and ions, metabolism of cyclic nucleotides, and so on cannot be accounted for by an action exclusively initiated at the level of the cell nucleus. The generalisation that polypeptide hormones act at the cell surface whereas small molecular weight hormones act within the cell is a gross over-simplification, as far as the latter class of hormones are concerned; after all, most actions of catecholamines can be satisfactorily explained on the basis of their interaction with plasma membrane receptors associated with adenylate cyclase⁵⁸. One has, therefore, to consider the possibility that the final expression of a growth and developmental hormone may result from a cooperative action generated by simultaneous or sequential but independent interactions with more than one nuclear and extranuclear sites.

The above discussion does not diminish the role of the nucleus in the action of thyroid or steroid hormones nor of the importance of continuing with hormone-binding studies. Nor is it implied that receptors or acceptors of steroid hormones are of little consequence in hormone action. Indeed, increasing evidence is now gathering from genetic studies that the cytosol-nuclear translocation and the nuclear localisation of steroid hormone are intimately associated with their capacity to induce the synthesis of specific proteins^{59,60} and a similar analysis of responsiveness to thyroid hormones would help clarify some of the ambiguities raised in this paper concerning their binding to nuclear and extranuclear cellular components. What can be said is that thyroid hormones do not interact with their target cells in the same manner as do steroids and that the current emphasis on their nuclear site of action based on binding studies with tri-iodothyronine *in vitro* may not reveal a balanced picture of the location and distribution of true receptors and, therefore, the initial events leading to the physiological action of these hormones.

Detailed studies on the subcellular and subnuclear distribution of thyroid hormone binding sites will soon be published elsewhere.

I thank Miss Betty Baker for technical assistance, Mr Martin Wisher for preparation of plasma membranes and liver perfusion, Dr Gordon Shore for preparation of inner mito-

chondrial membranes, and Dr Kathy Beckingham Smith for discussions and collaboration.

A major geothermal anomaly in the Gulf of California

Lawrence A. Lawver

University of California, San Diego, Marine Physical Laboratory of the Scripps Institution of Oceanography, La Jolla, California 92037

David L. Williams

US Geological Survey, Denver, Colorado 80225

Richard P. Von Herzen

Woods Hole Oceanographic Institution, Woods Hole, Massachusetts 02543

We have mapped a 3-km wide, high heat flow anomaly with a maximum value of $30 \mu\text{calorie cm}^{-2} \text{ s}^{-1}$ within a zone of seafloor extension in the central Gulf of California. From seismic reflection data and thermal modelling we suggest that the anomaly is caused by a 1-km wide basaltic intrusion which is roughly 100 m deep and less than 18,000 yr old.

SEAFLOOR spreading associated with the East Pacific Rise can be extended to inside the mouth of the Gulf of California, by correlating magnetic lineations¹. Further into the gulf the magnetic lineations are either disturbed by the thick sedimentary cover, or the lineations are weak or non-existent due to an intrusive or cooling mechanism that is unfavourable to their formation². The San Andreas fault to the north is recognised as the major part of the boundary between two large plates—the Pacific and North American. The Gulf of California is a transitional region between predominantly seafloor spreading to the south and totally transform fault motion to the north. The lack of identifiable magnetic anomalies in the gulf makes it necessary to look for other evidence to support the idea of seafloor extension. The pole of rotation for the Pacific-North American plates is 50.9°N , 66.3°W (ref. 3). The trend of the gulf differs sufficiently from a small circle about this pole to require *en echelon* offset of the transform faults and thus requires some seafloor extension in the gulf. Large heat flow⁴ and microseismicity⁵ in the basins also suggest that the gulf is undergoing extension as well as transform fault motion.

Shepard⁶ recognised the similarity between the Gulf of California and the Red Sea and mapped the *en echelon* strike-slip faults and rhombic nature of the basins. Rusnak, Fisher and Shepard⁷ related the opening in the gulf to the strike-slip motion of the San Andreas fault and deduced a figure of 260 km of opening, with Cabo San Lucas originally near Banderas Bay, Sinaloa. They considered the central depressions in the Guaymas and Farallon Basins to be extensional features due to their perpendicularity to the strike-slip faults. Larson¹ deduced a half-spreading rate of 30 mm yr^{-1} by correlating magnetic anomaly patterns at the mouth of the gulf. Lawver *et al.*⁴ reported on 13 new heat-flow measurements in the Guaymas Basin bringing the then total to 16, with three from Von Herzen⁸. Large values were found in the north-east central Guaymas Deep, $>5 \text{ HFU}$ ($>200 \text{ mW m}^{-2}$) with the greatest being 7.2 HFU (300 mW m^{-2}) near a 160-m high mound in the deep.

Measurements and techniques

The most recent cruise, in October 1974, collected 58 new heat-flow measurements in the Guaymas Basin. Most of the work

was concentrated in the north-east Guaymas Deep but some of the most interesting results came from the south-west Guaymas Deep (Fig. 1).

The thermal gradients were measured using the Woods Hole Oceanographic Institution multipenetration heat-flow probe⁹. It consists of a 2.5-m probe with three outrigger thermistor probes at 1-m intervals. Acoustically telemetered data were recorded on a precision depth recorder aboard the RV Agassiz of the Scripps Institution of Oceanography. Navigation consisted of radar fixes and depths later plotted on the satellite navigated bathymetric chart of G. F. Sharman (unpublished). The radar navigation was accurate to about 500 m, with relative positions between individual measurements being better ($\sim 250 \text{ m}$), see Fig. 2. The sediments in the Guaymas Basin are extremely uniform and consist almost solely of green hemipelagic mud. Thermal conductivities were assumed from measurements made on previous cruises⁴. The water content is very high in the near-surface sediments causing the conductivity in those shallower than 50 cm to be about $1.5 \times 10^{-3} \text{ calorie } ^\circ\text{C}^{-1} \text{ s}^{-1} \text{ cm}^{-1}$ ($0.60 \text{ W m}^{-1} \text{ K}^{-1}$). The conductivity below 50 cm is assumed to be reasonably constant, based on the findings of Lawver *et al.*⁴ and is taken to be $1.71 \times 10^{-3} \text{ calorie } ^\circ\text{C}^{-1} \text{ s}^{-1} \text{ cm}^{-1}$ ($0.71 \text{ W m}^{-1} \text{ K}^{-1}$). The heat-flow values are shown on the diagram in Fig. 3 and listed in Table 1.

The average sedimentation rate in the central part of the Guaymas Basin is approximately 2.0 m per 1,000 yr (ref. 10). This high sedimentation rate depresses the surface heat flow, requiring approximately a +12% correction according to Fig. 9 of ref. 11. From the seismic reflection profiles in Fig. 5, the south-west Guaymas Deep seems to be underlain by basement which has intruded through older sediments, as evidenced by the apparent $0.8 \pm 0.2 \text{ s}$ thick sediment to the north and $0.6 \pm 0.1 \text{ s}$ thick sediment to the south. Later we show that the heat-flow anomaly is consistent with an intrusion of this geometry with an age of about $2 \times 10^4 \text{ yr}$. For this model, the anomaly is completely dominated by the transient cooling of the intrusion and the sedimentation rate has a negligible influence. For purposes of discussion no corrections will be made to the recorded heat-flow values.

Interpretation

Nearly every other region of active seafloor generation is almost devoid of sediments making heat-flow measurements there possible only in isolated sediment ponds. The available heat-flow values from these regions are apparently depressed by hydrothermal circulation. The heat-flow values measured in the Gulf of California are significantly higher than those measured on other spreading centres. Henyey (unpublished) measured a

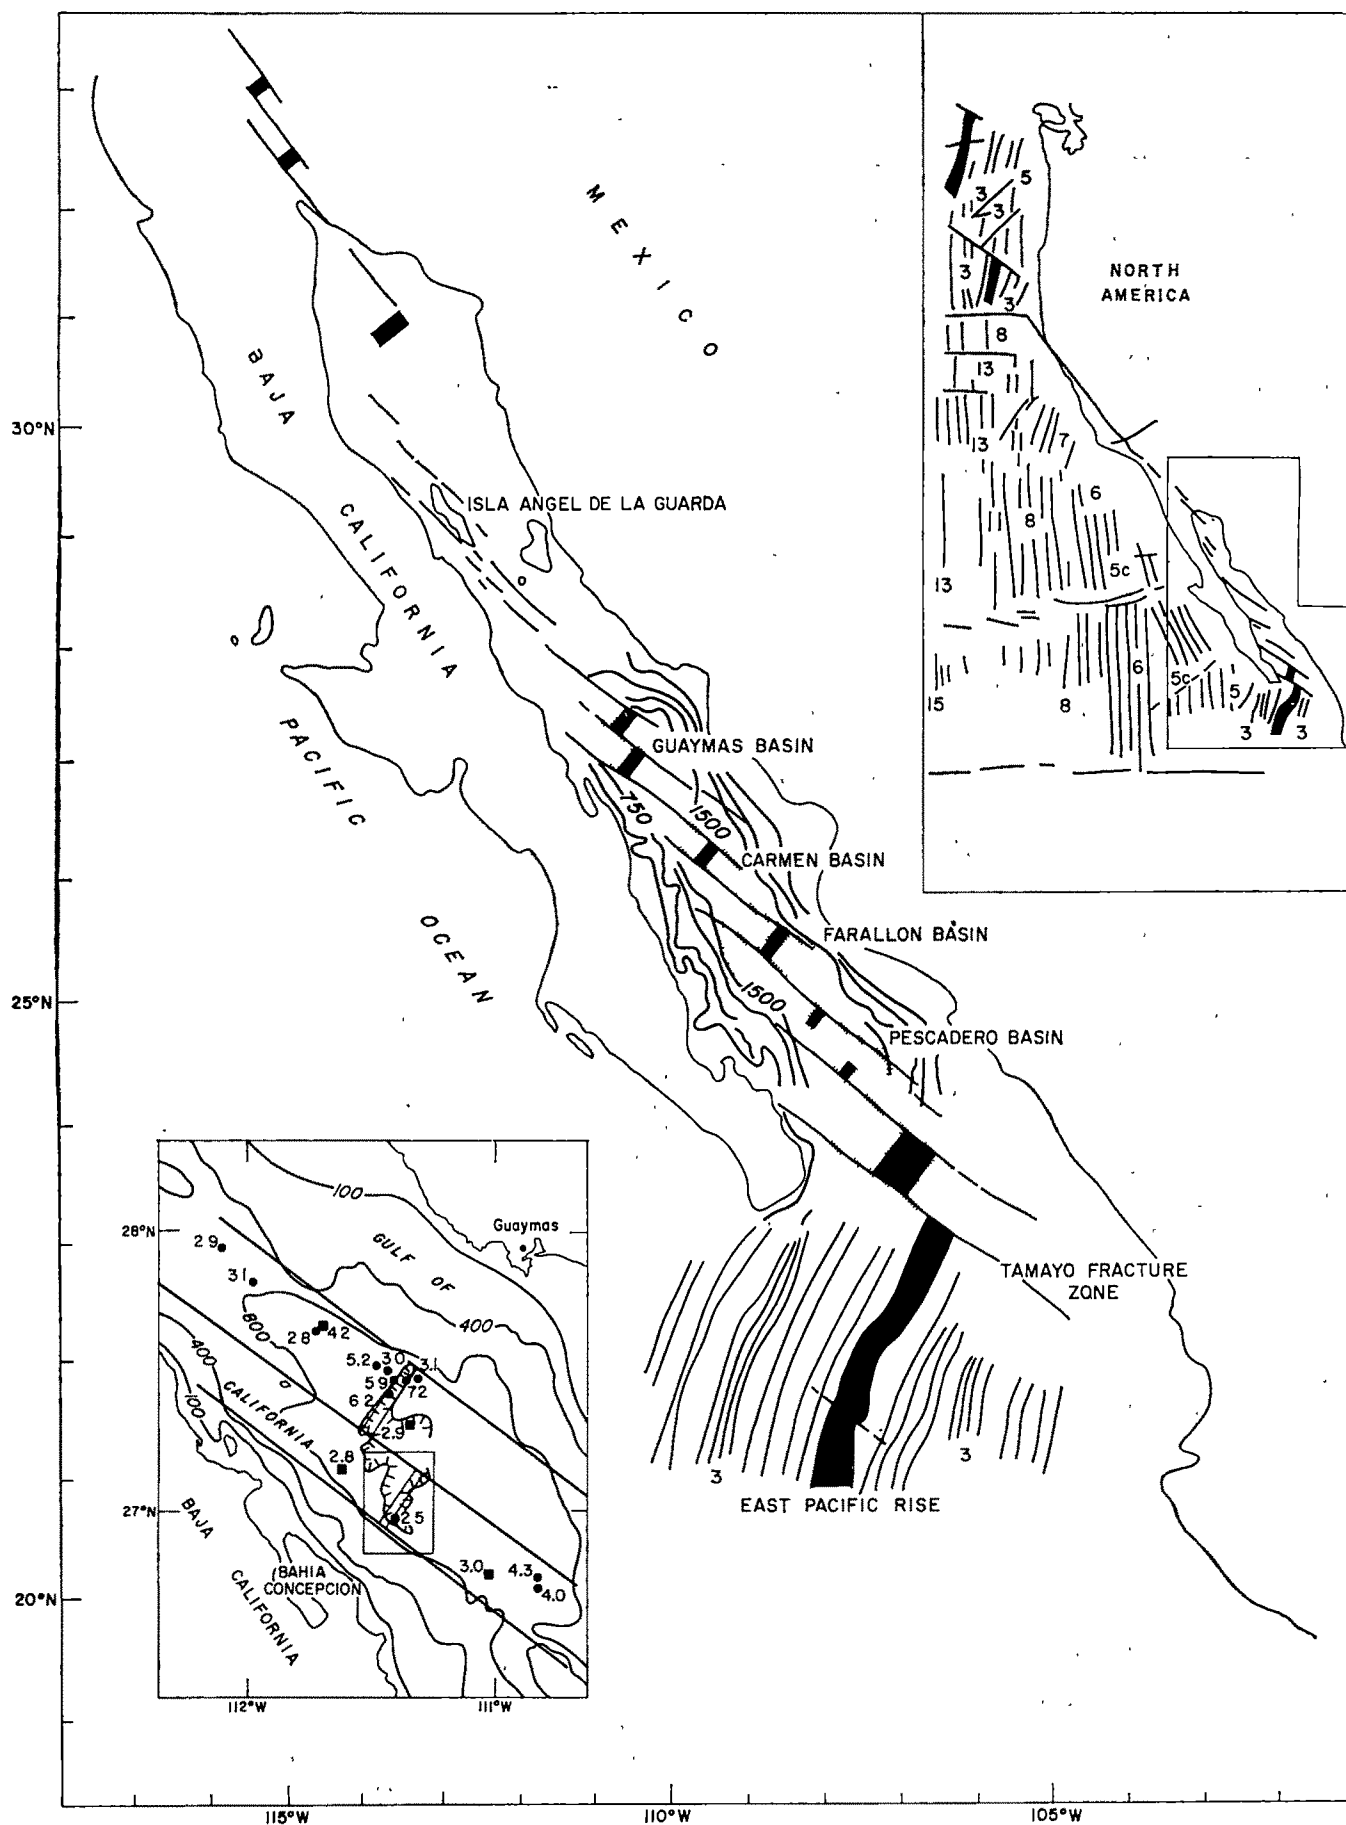

Fig. 1 Lineated magnetic anomalies at the mouth of the Gulf of California, from Larson¹. Generalised bathymetric lines in gulf in metres. Upper inset map with magnetic anomaly numbers from Atwater²⁰. The lower inset is a generalised diagram of the Guaymas Basin from Lawver *et al.*⁴ showing heat-flow values, in $\mu\text{calorie cm}^{-2} \text{ s}^{-1}$. Squares indicate values from Von Herzen⁸. Circles from Lawver *et al.*⁴. Box shows area of detailed heat-flow measurements shown in Fig. 2. Heavy lines and stippled areas mark transform faults and areas of active generalised extension, respectively.

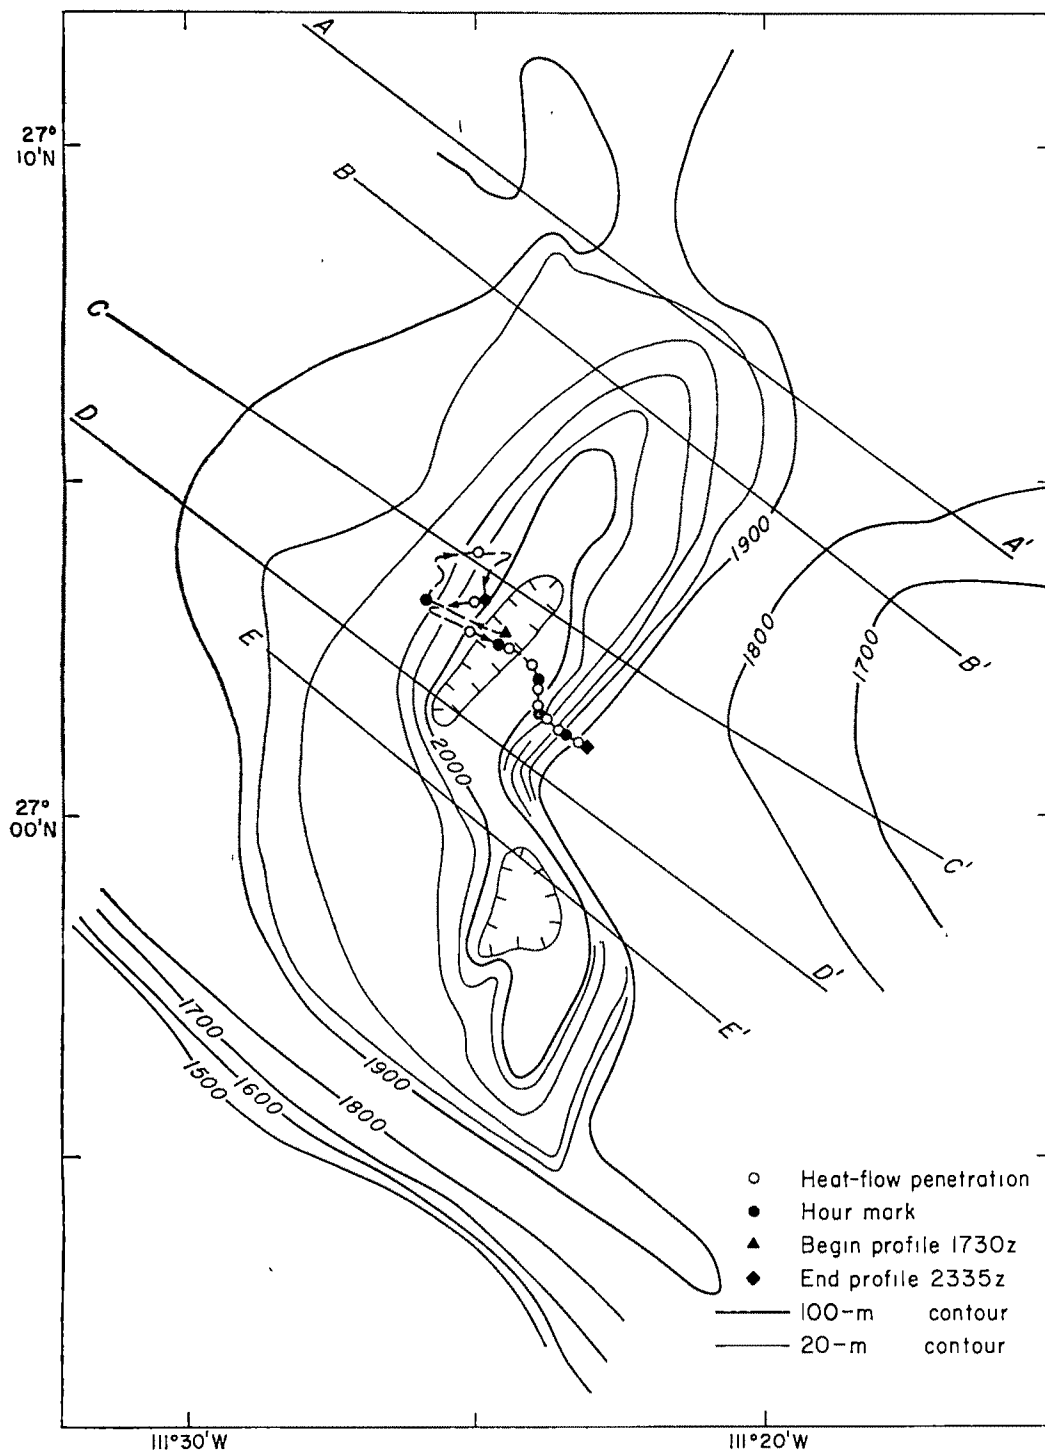

Fig. 2 Detailed chart of heat-flow survey of the south-west Guaymas Deep in corrected metres. Bathymetry from G. Sharman (unpublished). The values progressed from the north-west side of the depression to the south-east side. Seismic reflection profiles A-A' to E-E' indicated by solid lines are shown in Fig. 5.

value of 35.8 HFU ($1,450 \text{ mW m}^{-2}$) in the Ballenas Channel in the northern gulf but this may be an isolated hot spring.

The heat release associated with lithospheric creation for a spreading rate equivalent to that of the gulf is estimated to be at least 330 calorie s^{-1} per cm of ridge length within 35 km of the spreading centre¹² or an average heat flow of 47 HFU. At most oceanic spreading centres the rate is presumed much higher near the centre due to the faster cooling produced by hydrothermal circulation (compare ref. 12). The Gulf of California is different because the actively spreading zone may be losing heat through the sea floor to a greater extent by conduction because of its unusually thick and continuous sedimentary cover.

Figure 4 shows all the 26 published and new heat-flow values in the Guaymas Basin plotted against distance from the presumed most recent spreading centre. Additional heat-flow

values in the Guaymas Basin to be discussed in a subsequent paper reinforce the basic shape of the curve in Fig. 4. It is unusual that the background heat flow for the Guaymas Basin is remarkably regular at 3.4 ± 0.5 HFU for the total length of the basin. The central deep coincides with a higher heat-flow zone less than 20 km wide.

This distribution of conductive heat flow does not fit the theoretical models for a conductively cooled lithosphere (see ref. 13). As can be seen in Fig. 4, the observed heat-flow values average less than half of the predicted value. Two factors, prevalent in the Gulf of California, would tend to make the measured values lie below the theoretical curve. First, the theoretical models assume continuous intrusion whereas in the Gulf of California there is evidence that the location of spreading centres changes discontinuously with time. This idea was first advanced by Bishoff and Henyey¹⁴ on

Fig. 3 Profile across the Guaymas Deep showing the heat-flow (HFU) values and the shape of the anomaly found.

the basis of seismic reflection profiles. It is supported by our heat-flow measurements and the reflection profiles shown in Fig. 5. At (a) on profile D-D' (Fig. 5), there is a slight depression which has not been completely filled with sediment; it has an uncertain age relationship to the central intrusion. Probably the depressions are in fact grabens caused by the pulling apart of the basement, resulting in an intrusion and a thinning of the overlying sediment (Fig. 3, ref. 21). The weight and shear strength of the sediments compared with water may cause the intrusion to slow and stop before it reaches the surface. This effect of the sediment may even cause the site of intrusion to change discontinuously rather than remaining fixed as at a normal spreading centre. The second factor that may affect the heat flow is that the ratio of the widths of spreading centres to the length of transform faults is much less in the Gulf of California than in more normal oceanic spreading areas. This could lead to significant lateral heat transfer. Although these factors redistribute heat to the flanking regions and away from the actively spreading locations, the total heat loss remains approximately the same and thus will not explain the great discrepancy between the predicted and observed heat flows.

Assuming that seafloor spreading applies in the gulf, the most plausible explanation for the discrepancy is hydrothermal heat loss even though there is a thick sediment cover. The existence and importance of hydrothermal convection in the basement have been discussed by numerous investigators (see reference lists in refs 12 and 15). The porosity and permeability would be related to dike contacts, the dissolution of minerals by thermal waters, the horizontal component of thermal contraction, and faulting. In the gulf the evidence is not as compelling as it is at other spreading centres. There is no evidence of numerous low heat-flow values and the large scatter in ob-

served values that have supported previous hydrothermal circulation hypotheses. We made approximately 50 km of near-bottom horizontal water temperature profiles (see ref. 12) in the north-east Guaymas Basin but failed to detect any temperature anomalies that might be associated with hydrothermal vents. Evidence for sediment that was more metalliferous than normal was found only in the southernmost basin of the gulf (P. Wilde, personal communication). Since this basin is nearest to the East Pacific Rise and has a much thinner sediment cover¹⁸ it is more likely to be subject to hydrothermal discharge through the sediment surface. In the heavily sedimented Guaymas Basin, where the sediments are assumed to be relatively impermeable and there is very little expression of faulting in the surface sediments, it is hard to imagine the free convection that Williams *et al.*¹² found on the Galapagos spreading centre.

Thermal modelling

With the line drawings of seismic reflection profiles crossing the south-west Guaymas Deep (shown in Fig. 5), available as control, the heat-flow data were inverted under the assumption of conductive cooling. We first used Horai's model¹⁷ for a dike intruded instantaneously and remaining at a constant temperature for infinite time. This model yields a 1.6-km wide intrusion with a depth to its top of 220 ± 30 m, using a background heat flow of 3.4 ± 0.5 HFU. But this gives either an unacceptably high surface thermal gradient (5°C cm^{-1}) or a temperature too low for molten rock (400°C). This result implies that the measured heat-flow values are not due to a constant temperature intrusion but rather to a transient cooling process. Therefore, we used Simmons¹⁸ method for modelling the transient cooling of a dike, which is a variation of that given by Carslaw and Jaeger (ref. 19, p. 256). The temperature for a dike is given as:

$$T(x, y, z, t) = (S/8) E(x, x_1, x_2) E(y, y_1, y_2) \{ E(z, z_1, z_2) + E(z, -z_1, -z_2) \}$$

where S = source strength, which for a three-dimensional source is simply the temperature at the time of the intrusion, here assumed to be $1,100^\circ \text{C}$; x_1 and x_2 are coordinates defining the width of the dike; y_1 and y_2 give the lateral extent of the dike; z_1 and z_2 are the depths to the top and bottom respectively and E is a dimensionless function defined as:

$$E(\xi, \xi_1, \xi_2) = \text{erf} \frac{\xi - \xi_1}{(4kt)^{1/2}} - \text{erf} \frac{\xi - \xi_2}{(4kt)^{1/2}}$$

where t is the time after intrusion and k is thermal diffusivity. If one assumes y_1 and y_2 are large, greater than $3(4kt)^{1/2}$, then $E(y, y_1, y_2)$ is two. For a time of 10^4 yr the absolute value of y_1 or y_2 would have to be larger than 0.8 km. Using Figs 2 and 5, it seems that $y_1 = -2.0$ km and $y_2 = 6.0$ km. z_2 is the

Table 1 Heat-flow data

Station no.	Latitude (°N)	Longitude (°W)	Water depth (corrected m)	T	P	N	K	Q

12.7	27°02.0'	111°24.0'	2,012	2.82	2.7	1	1.71 (0.72)	29.9 (1251)*
12.8	27°01.8'	111°23.9'	2,010	2.82	2.7	3	1.71 (0.72)	13.6 (569)
12.9	27°01.5'	111°23.7'	1,952	2.83	2.7	3	1.71 (0.72)	5.3 (222)
12.10	27°01.3'	111°23.4'	1,898	2.83	2.7	3	1.71 (0.72)	4.8 (201)

T is bottom water temperature ($^\circ \text{C}$); P is estimated sediment penetration (m) of the lowermost probe used in gradient measurements; N is the number of thermistors used for sediment temperature gradient measurements; K is the thermal conductivity in 10^{-3} calorie $^\circ \text{C}^{-1} \text{cm}^{-1} \text{s}^{-1}$ ($\text{W m}^{-1} \text{K}^{-1}$) (All values are assumed); Q is the heat flow in 10^{-6} calorie $\text{cm}^{-2} \text{s}^{-1}$ (10^{-3} W m^{-2}).

*Only one thermistor on scale.

Fig. 4 Summary of the previous published values and the ten new values. The background heat flow is roughly 3.4 ± 0.5 HFU (135 ± 20 mW m $^{-2}$). The heat flow anomaly is strikingly regular directly over the depressions confirming them as the locus of present intrusive activity.

depth to the base of the dike which we assume is large in comparison to z_1 . If z_2 is just twice z_1 , it affects Q_z only 2%.

Simmons (ref. 18, equation 17) gives the surface heat-flow distribution as:

$$Q_z \big|_{z=0} = \frac{-KS}{2(\pi kt)^{1/2}} E(x, x_1, x_2) [\exp(-z_1^2/4kt) - \exp(-z_2^2/4kt)]$$

In this model, the same thermal properties are assumed for the dike as for the material into which it is intruded. We assume the thermal properties of sediments to be more realistic because the cooling is probably dominated by the insulating properties of the sediment. But the igneous body should be able to release heat faster, and should be younger than our solutions indicate. In Fig. 6 however, we show that both sediment and igneous rock thermal properties can be made to match the data. We have taken a conductivity, K , of 2×10^{-3} calorie °C $^{-1}$ s $^{-1}$ cm $^{-1}$ (0.83 Wm $^{-1}$ K $^{-1}$) and diffusivity, k , of 2.35×10^{-3} cm 2 s $^{-1}$ to approximate a slightly compacted sediment column²⁰. Even greater values might be expected considering the probable metamorphism of the sediments directly above the intruded body. From the seismic reflection profile D-D' shown in Fig. 5, it seems that the anomaly is due to an intrusion

that is directly underneath the depression. From Fig. 5 the intrusion seems to be present and approximately the same shape on profiles A-A' through D-D' and is vague but present on E-E'. The intrusion seems to extend from one transform fault to the other. On profile D-D', closest to the profile of heat-flow stations, the depth to the top of the intrusion seems to be about 120–200 m. Figure 6 shows that using a depth of 200 m and removing the background heat flow, our anomaly is closely matched with a width of 1.3 km, and an age of 17,000 yr. For this model a maximum heat flow of 53 HFU would be reached at about 2,700 yr after the emplacement of the intrusion. The observed heat-flow maximum of 30 HFU is found twice for any model that assumes $z=200$ m, once at about 1,000 yr and again at 17,000 yr. The earlier time value seems unacceptable because it produces a very steep-sided anomaly as shown in Fig. 6, unlike the profile measured. If one assumes a depth to intrusion of 100 m, then an age of 18,000 yr very nearly models the observed anomaly. A greater depth to the intrusion is more difficult to model with thermal properties of sediments, although the thermal properties of the intrusive rock will fit the observed curve for a depth to intrusion of slightly greater than 500 m.

The seismic reflection profile indicates that the base of the intrusion may be 4 km in width, equivalent to about 65,000 yr of spreading at the half-rate of 30 mm yr $^{-1}$. It seems plausible to assume that the most recent intrusion is simply the latest in a continuing series of recent intrusions now totalling 4 km. If the most recent intrusion was emplaced into an older intrusion not at thermal equilibrium then our model would be less representative and much more recent ages of intrusion are possible. A 1.3 km wide intrusion would account for 21,000 yr of spreading. Since we have more than 42 m of sediment (2 m per 1,000 yr for 21,000 yr), we assume that the intrusion has always been covered. Hydrothermal cooling which might account for removal of about half the heat would be roughly equivalent to doubling the thermal conductivity (similar to the conductivity

Fig. 5 Line drawings of seismic reflection profiles. Line of profiles shown on Fig. 2. In profile D-D', *a* indicates a possible depression that is either just forming or is being filled and *b* indicates the area of the main heat-flow anomaly.

Fig. 6 Results of Simmon's¹⁸ model for heat-flow produced by a cooling intrusion.

of the intrusive rock). Although there are many variable parameters not defined by our data, the results from the model can be summarised as indicating an intrusion approximately 1.0 km wide, beneath 150 ± 100 m of sediments and less than 18,000 yr old.

Conclusions

Our findings allowed us to use heat-flow measurements to model a reasonably young intrusion, something that is rarely achieved. It does seem reasonably certain from our results that the gulf is not being opened by a continuing constant intrusion as is presumed at most oceanic spreading centres. Discontinuous and episodic intrusions into a thick sedimentary cover would explain the lack of magnetic anomalies in the gulf. Apparently the intrusion is continuous between transform faults and is believed contemporaneous.

The Gulf of California has an average sediment depth of

about 1 km (ref. 16). This, coupled with the high background heat flow, suggests that temperatures of 200 °C should generally be found near the sediment-rock interface. This is in addition to large areas where the thermal gradient is several times as high. If the upper regions of the basement are as porous and permeable as we believe, the Gulf of California would be one of the Earth's most important geothermal resources. This theory, though, can only be tested by drilling.

More measurements are needed in this area to trace the assumed lateral extent of the anomaly. Since the intrusion seems to be continuous between the transform faults, one would hope that the heat flow remains uniformly high in this region. Other sites in the Guaymas Basin and particularly the Farallon Basin to the south may be undergoing current intrusion and should be investigated.

We thank Captain Larry Davis and the crew of the RV Agassiz for assistance. Richard Zuck of Woods Hole, Massachusetts, and Ken Green of MIT assisted with the instrumentation and measurements. M. A. Landin, T. D. Lara, R. N. Hernandez, and A. Velasco of the Ciencias Marinas of Ensenada, Baja California, assisted us with navigation work. Richard Schwartzlose of Scripps organised the cruise. We thank Vic Vacquier and John Slater for comments. The Mexican Government extended us permission to work in their waters. This study was supported largely by grants from the US National Science Foundation.

Three-dimensional model of purple membrane obtained by electron microscopy

R. Henderson & P. N. T. Unwin

MRC Laboratory of Molecular Biology, Hills Road, Cambridge CB2 2QH, UK

A 7-Å resolution map of the purple membrane has been obtained by electron microscopy of tilted, unstained specimens. The protein in the membrane contains seven, closely packed, α -helical segments which extend roughly perpendicular to the plane of the membrane for most of its width. Lipid bilayer regions fill the spaces between the protein molecules.

THE purple membrane is a specialised part of the cell membrane of *Halobacterium halobium*¹. Oesterhelt and Stoekenius² have

shown that it functions *in vivo* as a light-driven hydrogen ion pump involved in photosynthesis. It contains identical protein molecules of molecular weight 26,000, which make up 75% of the total mass, and lipid which makes up the remaining 25% (ref. 3). Retinal, covalently linked to each protein molecule in a 1:1 ratio is responsible for the characteristic purple colour³. These components together form an extremely regular two-dimensional array⁴.

We have studied the purple membrane by electron microscopy using a method for determining the projected structures of unstained crystalline specimens⁵. By applying the method to tilted specimens, and using the principles put forward by

Fig. 1 Part of the three-dimensional reciprocal lattice showing the geometry of the lattice lines in the hexagonal space group P3. a^* , b^* and c^* are the reciprocal lattice vectors. a^* and b^* lie in, and c^* is perpendicular to the plane of the membrane. A central section which is perpendicular to the incident electron beam has been drawn through the lattice. The intersection of this central section with the reciprocal lattice is determined by the angle of tilt and the axis about which the membrane is tilted. Individual diffraction patterns and micrographs provide the amplitudes and phases in this section at the points shown. z^* represents the coordinate along the c^* direction of one of the points. The angle of tilt was measured to within 2° for each of the specially modified, tilted specimen holders, and the direction of the tilt axis on the photographic plate was established during operation of the microscope. However, estimates based on the geometry of the spacings of the lattice points (for high tilt angles), the variation of the degree of underfocus across the plate (for low tilt angles), and least squares refinement against data obtained at high tilt angles (for diffraction patterns) provided more accurate figures which were used in the calculation. The accuracy of measurement of both the amplitudes and phases depended on having sharp lattice lines. We therefore took care to ensure that, on the microscope grid, the membranes remained coherently ordered and flat to within $1/5^\circ$.

De Rosier and Klug⁶ for the combination of such two-dimensional views, we have obtained a three-dimensional map of the membrane at 7 Å resolution. The map reveals the location of the protein and lipid components, the arrangement of the polypeptide chains within each protein molecule, and the relationship of the protein molecules in the lattice.

Electron microscopy and diffraction

The purple membrane was prepared under normal conditions from cultures of *H. halobium*³ and applied to the microscope grid in the presence of 0.5% glucose. The purified membranes are mostly oval sheets up to 1.0 μm in diameter and about 45 Å thick^{4,7}. The array of molecules making up these sheets is accurately described⁷ as an almost perfect crystal of space group P3 ($a = 62$ Å) with a thickness of one unit cell only in the direction of the c axis. A single membrane thus contains up to 40,000 unit cells; that is 120,000 protein molecules (three per unit cell).

These large periodic arrays from which electron diffraction patterns and defocused bright field micrographs are recorded⁵ enable us to overcome the principal problem normally associated with high resolution electron microscopy of unstained biological materials; that is, sensitivity to electron damage⁸. Only a small number of electrons can pass through each unit cell before it is destroyed, but because of the large number of unit cells, the information in the diffraction patterns and micrographs is sufficient to provide a picture of the average

unit cell. The micrographs recorded with such low doses of electrons appear featureless, since the statistical fluctuation in the number of electrons striking the plate is large compared with the weak phase contrast ($<1\%$) produced by defocusing. As a result, analysis of each micrograph by densitometry and computer processing⁵ is required to combine the information from individual unit cells.

Solution of the three-dimensional structure of the purple membrane requires the determination of the amplitudes and phases in three dimensions of the Fourier terms into which it can be analysed. The diffraction pattern or Fourier transform of the membrane is not a three-dimensional lattice of points as is the case with a normal crystal, but since it is only one unit cell thick, a two-dimensional lattice of lines which are continuous in the direction of c^* (that is perpendicular to the membrane). A single electron diffraction experiment therefore gives rise to a two-dimensional pattern of spots which correspond in their intensities to the square of the amplitudes of the transform along a central section through the three dimensional transform of the membrane (Fig. 1). Similarly, an electron micrograph contains information about the phases (and about the amplitudes, but less accurately than does the diffraction pattern) in the central section. Previously⁶, we were able to determine the projected structures of both the purple membrane and thin catalase crystals from the amplitudes (obtained by electron diffraction) and phases (by Fourier analysis of micrographs) along the single central section through the transform parallel to the plane of the object.

Here, we have collected data similar to those obtained previously but from 15 diffraction patterns and 18 micrographs (actually pairs of micrographs, see ref. 5) of membranes tilted at angles from 0° to 57° to the incident electron beam, to determine the amplitudes and phases at a number of points along each of the lattice lines. These data provided estimates of the continuous variation of the transform along the lines. By sampling the continuous curves at appropriate intervals, it was then possible to calculate the structure as if for a three-dimensional crystal with some arbitrary c -axis dimension greater than the membrane thickness. This method of combining two-dimensional images was proposed originally by De Rosier and Klug⁶ for a general object, although in this case we have made use of electron diffraction patterns as well.

The diffraction patterns provided 1,800 independent intensity measurements which were combined to give continuous curves, such as those shown in Fig. 2, for each of the 36 crystallographically independent lattice lines out to a resolution of 7 Å.

Fig. 2 Values of intensity and phase along two lattice lines, obtained respectively from the diffraction patterns and images using the geometry shown in Fig. 1. Smooth curves were drawn through the points to give reliable intensities and phases at suitably fine sampling intervals (0.01 Å^{-1}) in z^* . These values were used to compute the three-dimensional structure.

Fig. 3 Schematic diagram showing the region of reciprocal space contributing to the three-dimensional Fourier map. Part of the boundary of the 7 Å sphere is indicated. The region shown, which includes 63% of the total volume of this sphere, includes almost all the strong diffraction peaks to 7 Å, with the principal exception of the axial (0,0) lattice line (but see text).

Because of the distribution of intensity in the transform⁷, due to real features in the structure, very little diffracted intensity (none greater than 1/50th of the strongest intensity) occurred at values of z^* greater than 0.08 Å^{-1} for any lattice line.

With the electron micrographs compensation for the effects of defocus was rather more complicated than in the case of untilted specimens⁸. Since the membranes we studied were at least 5,000 Å in diameter, different parts of the membrane in a tilted specimen were situated at significantly different distances from the objective lens. As a result, the phase contrast transfer function, which depends on the degree of underfocus of this lens, varied across the image. The correction of the contrast of the image could not be made after transforming the image by altering the phases of the Fourier components of the image, as was done previously, but instead had to be carried out at an earlier stage, so that different parts of the image where the contrast is positive or negative could be made to combine constructively, and thereby yield, on transformation, the correct phases for the object. This procedure was conveniently carried out between the execution of the first and second dimensions of the Fourier transformation having ensured that the images were densitometered parallel to the tilt axis. The contrast along each scan line could then be corrected by multiplying the one-dimensionally transformed data by the contrast transfer function, $-2 \sin \chi$ (see ref. 5) for each reflection, so that the computed phases had the correct sign for the object, and gave the maximum signal-to-noise ratio. The phases were then combined image by image after refining the phase origin of each image so that the best agreement of its phases with all previously accumulated phases was obtained. By starting with the untilted data with the phase origin at one of the threefold positions, and adding the phases from images with smaller tilt angles first, the maximum accuracy in combining the phases was ensured. This procedure also meant that the phase origin for the combined three-dimensional data ended roughly in the middle of the membrane on one of the threefold axes. The average phase error in a single measurement estimated from the differences between those of the 1,000 independently recorded phases having similar values of z^* was less than 20° , as found previously⁵. As with the intensity data, continuous curves could be drawn through these phase measurements (Fig. 2).

The intensity and phase curves were sampled at intervals of 0.01 Å^{-1} to provide Fourier terms from which to calculate the three-dimensional map. This sampling interval is more than sufficiently fine to ensure an accurate representation of a structure only 45 Å thick.

Three-dimensional potential map

The map (Fig. 4) was a Fourier synthesis of 365 crystallographically independent terms which extended to a resolution

of 7 Å in the plane of the membrane, but which included only terms with spacings greater than 14 Å perpendicular to it. There were two reasons for the asymmetrical distribution of Fourier terms. First, the distribution of intensity in the transform of the membrane is such that the diffraction beyond spacings of 7 Å in the plane of the membrane, and about 20 Å perpendicular to it, is weak and therefore difficult to measure with the limited total diffraction available from membranes only $1 \mu\text{m}$ in diameter. The average intensity in these regions by X-ray diffraction⁷ is 7–10 times lower than the in-plane diffraction near 10 Å , and by electron diffraction we find no intensity greater than 1/50th of the strongest diffraction at values of z^* greater than 0.080 Å^{-1} . Second, the use of tilt angles up to some limiting angle, in this case 57° , meant that a conical region of reciprocal space was unmeasured. The volume of reciprocal space finally included is shown schematically in Fig. 3. Although a considerable volume of the 7 Å sphere is missing (37%) the effect of its inclusion in the map would be very small since the X-ray diffraction pattern indicates that the amplitudes of the Fourier components in the missing regions are small. Therefore, since the map includes all the strong terms present to 7 Å resolution, it provides an accurate representation of the dominating features of the structure to this resolution.

As a further check on the effect of leaving out some of the near axial reflections, a second map was calculated which included the profile diffraction determined by X rays. The amplitudes were obtained from the published X-ray profile

Fig. 4 Part of the three-dimensional potential map showing a region 50 Å thick spanning the membrane. The sections above and below this region contain no features higher than one contour level. The absolute hand is determined by the known direction of specimen tilt. The view shows protein molecules grouped around one of the threefold axes. The probable boundary of one of them is indicated by the broken line. The angle of view is such that the α helices furthest from the threefold axis partly overlap in the protein molecule outlined, but are seen almost end-on in the one on the right.

of Blaurock and Stoeckenius⁴ by sampling at 0.01 \AA^{-1} intervals, and scaled to our data by comparing the profile intensity with that of the (1,1) ring in an unoriented X-ray powder pattern. The phases were assumed to be those of a symmetrical membrane⁴ with the origin in the middle. The inclusion of the Fourier terms out to 0.05 \AA^{-1} made little difference to the map but, as would be expected, slightly raised the overall level of the contours on each side of the membrane (by about one contour level). The axial (0,0) line is by far the strongest region not included in our map, so clearly the effect of excluding the remaining unmeasured volume of reciprocal space is small.

Since the amplitudes and phases used to calculate the present map are derived from the scattering of electrons, the physical quantity which it represents is, strictly, the electrical potential inside the membrane. At this resolution, however, the potential is roughly proportional both to the electron density, as would be found for instance by X-ray analysis, and to the atomic number. High density features therefore correspond to the presence of denser groupings of atoms.

Structure of the membrane

The appearance of the map is dominated by numerous rod-shaped features aligned perpendicular to the plane of the membrane. There are seven rods in each asymmetric unit of the crystal and they are packed 10–12 \AA apart. Adjacent rods are slightly inclined to one another at various angles from 0° to 20° and they are all roughly 35–40 \AA long. In view of the existence^{7,9} in the X-ray diffraction pattern of strong axial reflections at 1.5 \AA and 5 \AA which are characteristic of the α -helix, there is little doubt that the seven rod-shaped features in the map are α -helices which extend perpendicular to the membrane for most of its width. Since the protein has a molecular weight of 26,000 (ref. 3), it follows that the α -helices make up 70–80% of the polypeptide. The connectivity of the helices, however, cannot be discerned unambiguously at this resolution.

The tentative boundary of an individual protein molecule indicated in Fig. 4 is the one most likely to be correct since it surrounds regions of the protein with maximum connectivity and it is this part of the map which we have used to make the model shown in Fig. 5. The overall dimensions of the protein in our model are $25 \times 35 \times 45 \text{ \AA}$, with the longest dimension perpendicular to the plane of the membrane and parallel to the helices. The three protein molecules which are most intimately in contact are grouped round the threefold axis in an interesting manner. Three of the seven α helices in each protein molecule are nearer the centre of the group giving an inner ring of nine helices which are all 10 \AA (± 1) apart and in contact with one another. The other four helices in each protein combine to make an outer ring of twelve which surround the inner nine. The outer helices are all slightly more inclined to the perpendicular than the inner ones, and are not all in contact. The three most strongly tilted of these helices were not resolved in projection⁵, since they partly superimpose when viewed perpendicular to the plane of the membrane. The direction of tilting of the outer helices is consistent with the interlocking of the amino acid side chains from adjacent helices—that is the structure is a left-handed supercoil, as expected for a right-handed α helix¹⁰.

In the space in the middle of the ring of nine helices, we presume that a small number of lipid molecules is arranged in the classical bilayer configuration. This space has a diameter of about 20 \AA ; it is not a hole filled with solvent since a difference map using X-ray intensities from wet versus dry membranes is featureless. Evidence obtained from another difference map shows that UO_2^{+2} ions can bind to this region of the membrane, again suggesting that the space is filled with lipid. Similar arguments that a lipid bilayer must be present apply to the rather even density regions which make up the remainder of the membrane structure, filling up the space between the clusters of three protein molecules.

At this resolution we cannot detect the covalently linked

Fig. 5 A model of a single protein molecule in the purple membrane, viewed roughly parallel to the plane of the membrane. The top and bottom of the model correspond to the parts of the protein in contact with the solvent, the rest being in contact with lipid. The most strongly tilted α helices are in the foreground.

retinal molecule, which is thought, from measurements of the dichroism at 560 nm in oriented specimens⁴, to be aligned parallel to the plane of the membrane—that is, perpendicular to the helices.

The structure of the purple membrane protein and the way it combines with lipid to form a two-dimensional mosaic in which the protein and lipid pack neatly side by side, each with a thickness of about 45 \AA , gives experimental support to recent concepts^{11,12} of membrane structure based on less direct evidence. In particular, the protein is globular, is almost certainly exposed on both sides of the membrane, and is surrounded by lipids which are arranged in separate areas with a bilayer configuration. The purple membrane thus seems to provide a simple example of an 'intrinsic' membrane protein, a class of structure to which many molecular pumps and channels must belong. We would not be surprised if the simple arrangement of helices found here also occurs in some of these other intrinsic membrane proteins.

A full account of this work will be published elsewhere. We thank Dr J. Pilkington and the Royal Greenwich Observatory for help with and facilities for the densitometry of the micrographs, Chris Raeburn for modifying the specimen holders and Drs L. Amos, T. Horsnell, R. Ladner and T. Takano for computer programs. We also thank our colleagues in this laboratory, particularly Dr A. Klug, for comments on the manuscript.

letters to nature

Observations of X rays from near NGC6440

ON nine separate occasions between October 27, 1971, and January 6, 1973, the MIT instrument aboard OSO-7 scanned the region of sky within about 10° of the galactic centre. Subsequent analysis of this data, in the form of all-sky maps, led to the discovery of several previously unreported X-ray sources¹. The most intense of these, MX1746–20, was found at $\alpha = 17^h 46.0^m$, $\delta = -20^\circ 22.2'$ (1950.0) or, in galactic coordinates $l'' = 7.73^\circ$, $b'' = 3.76^\circ$. The 90% confidence contour for this position is a circle of radius approximately 0.26° . This uncertainty includes an estimate of the probable aspect error as well as statistical uncertainty.

The MIT instrument² consisted of two banks of five proportional counters sensitive from 1–60 keV. The mean intensities for each of the scans of the position of MX1746–20 are given in Table 1 for each of the four proportional counters for which useful data were obtained. The data for the low-energy counters are omitted in some cases because of contamination by solar X rays or because of the failure of one of the two lowest energy counters after August 2, 1972.

MX1746–20 is a highly variable X-ray source on time scales of months. Variations of at least a factor of 20 are observed. We have seen only weak evidence for variation on shorter time

of globular clusters as a function of angular separation from the galactic centre, we determined the probability of a chance coincidence of MX1746–20 with any globular cluster to be about 1%.

The distance to NGC6440 has not been well established although it is likely to be found close to the galactic centre. This hypothesis is supported by the galactic coordinates of the source and by its late spectral type (G5) which is believed to be typical of clusters around the centre of the Galaxy³. Assuming a distance of 10 kpc to MX1746–20, we derive a peak 1–10 keV X-ray luminosity of 3.4×10^{37} erg s⁻¹.

Like the previously discovered globular cluster X-ray sources^{3,5,6}, MX1746–20 is highly variable and its counterpart, NGC6440, is concentrated (concentration class V). This latter characteristic of the cluster adds credence to those theories of globular cluster X-ray emission which require high central densities to encourage the formation of binary systems (ref. 7 and unpublished work by A. C. Fabian *et al.*), or to provide a high enough escape velocity to cause a gas accretion rate sufficient to power the observed X-ray production from the vicinity of massive black holes (ref. 8 and J. Silk and J. Arons, unpublished).

Since all of the cluster X-ray sources discovered thus far are variable³, it may be that many more remain to be found. At

*The observed intensities may be converted to photon fluxes by the approximate formula $\Phi = \gamma/I$ where Φ = flux in photons cm⁻² s⁻¹ keV⁻¹, I = intensity in counts s⁻¹, and $\gamma = 0.15$ (1.0–1.5 keV), 0.0069 (1–6 keV), 0.0045 (3–10 keV), 0.0013 (15–40 keV).

scales although the statistical precision of our data hampers our ability to observe fluctuations less than about 5 counts s⁻¹ on time scales shorter than a day.

We were able to fit parameters describing the spectrum of MX1746–20 for the observations of January 1972. Because of the small number of data points available, however, we were unable to determine the nature of the spectrum unambiguously. For a trial thermal bremsstrahlung spectrum, a temperature of 7.7 ± 3.5 keV and a hydrogen column density of $1.1^{+1.0}_{-0.8} \times 10^{22}$ atoms cm⁻² were determined. For a power law spectrum, we found a photon spectral index of $2.1^{+0.8}_{-0.5}$ and a hydrogen column density of $5.3^{+3.0}_{-2.0} \times 10^{22}$ atom cm⁻².

A search of star catalogues and catalogues of interesting objects yielded only one likely candidate in the MX1746–20 error circle—the globular cluster NGC6440. NGC6440 is by far the most prominent object in the error circle and the only object brighter than $m_v = 10$, in spite of the high density of stars in the region. Using an empirical formula³ for the density

least two of the sources, MX0513–40 and MX1746–20, vary so greatly that they frequently fall below the level of detectability of the MIT OSO-7 instrument. We suggest that current and future satellite experiments, particularly those with high sensitivity, observe concentrated globular clusters from time to time since it is possible that a large fraction of them emit X rays on occasion.

Abell 478 and X-ray source 3U0405+10

THREE sightings of the faint X-ray source 3U0405+10 with the Ariel V sky survey instrument have produced an improved position, with the error box now containing Abell 478. This distance class 6 Abell cluster is the most distant X-ray source yet detected. It has a (2–20 keV) X-ray luminosity of $(5.4 \pm 1.1) \times 10^{45} \text{ erg s}^{-1}$.

The instrument detected X-ray emission from 3U0405+10 on October 28, 1974, with both high (2.4–19.8 keV) and low (1.2–5.8 keV) energy detector systems. Combining these two lines of position with a later cross scan, from the HE system on March 17, 1975, the revised position of 3U0405+10 has been derived; correcting the Uhuru count rate to the new position gives a slightly higher rate statistically consistent with the Ariel V results.

The sky survey experiment scans a strip of sky around the spin plane of the satellite. The response of the collimators is designed to produce long, thin lines of position for the sources detected. The high and low energy systems are canted by $\pm 25^\circ$ respectively to the spin axis direction so that a source seen in both systems will have an error box limited to the crossing of the two lines of position. The FWHM of the collimators is 0.73° in the spin plane and 10.6° along the line of position. The width of each line of position has been taken as the FWHM of the collimator divided by the significance of the signal above the background. This corresponds approximately to a 90% confidence that the source lies within the boundaries of any line. Table 1 lists the observations and Fig. 1 shows the new error box, together with that from the earlier Uhuru observations.

The refined error box now contains the cluster of galaxies Abell 478 (Fig. 2) which was just outside the 3U error box¹. Furthermore, the area of the error box is now reduced to 0.27 square degrees from our data alone; combined with the

Fig. 1 Three intersecting lines of position from presently reported Ariel V observations give error box shown by thick line. Also shown are previous Uhuru position of 3U0405+10 and centre of A478 (1950 coordinates).

Fig. 2 Ariel V error box superimposed on Palomar Sky Survey photograph. The brightest galaxy in the A478 cluster is clearly seen in the north-east corner of the box; the circle indicates the approximate extent of the cluster. (Photograph copyright National Geographic Society–Palomar Observatory Sky Survey.)

Uhuru observations this is further reduced to ~ 0.1 square degrees. We regard this improved location as confirming the association of A478 with the X-ray source 3U0405+10. From a positional correlation of all the rich clusters in the Abell catalogue with the actual 3U sources and with similar distributions of sources from 20 'fake' catalogues, J. N. Bahcall and N. A. Bahcall (see ref. 2) have concluded that there is no good evidence for the association of any of the most distant (distance class 5 or 6) Abell clusters with X-ray sources in the 3U catalogue. Specifically, their analysis for 3U sources with error boxes ≤ 5 square degrees produced four associations with distance class 5 and 6, whereas the 'fake' source catalogue gave 2.7 ± 1.5 associations. The fivefold reduction in the error box area of 3U0405+10 greatly increases the probability of a physical association with A478, a rough estimate based on the number density of clusters and of 3U sources now giving a probability in excess of 80%.

Taking Abell's redshift value of 0.18 for distance class 6 clusters³ and a Hubble constant of $60 \text{ km s}^{-1} \text{ Mpc}^{-1}$ gives a distance of 900 Mpc. If we take the mean energy of our measured flux to be 4.5 keV (as it would be for a spectrum like that of the Crab source) then the two high energy measurements, combined, give an X-ray luminosity (2.4–19.8 keV) of $(5.4 \pm 1.1) \times 10^{45} \text{ erg s}^{-1}$. This makes A478 the most distant X-ray source

Table 1 Observations of 3U0405+10 with Ariel V sky survey

Date	Energy band (keV)	No. of orbits summed	Incident flux* ($\text{erg cm}^{-2} \text{ s}^{-1}$)
October 28, 1974	2.4–19.8	18	$(4.6 \pm 1.2) \times 10^{-11}$
October 28, 1974	1.2–5.8	18	$(6.6 \pm 2.3) \times 10^{-11}$
March 17, 1975	2.4–19.8	27	$(6.9 \pm 2.8) \times 10^{-11}$

*Assuming spectrum like that of Crab source.

yet detected and also the most luminous of all the X-ray cluster sources. Interest in the apparent relationship between the X-ray luminosity of clusters and the velocity dispersion of their brighter individual galaxies (for example, ref. 4) makes it of considerable importance to measure the value for A478, which is inferred, to lie in the range $4,000\text{--}7,000 \text{ km s}^{-1}$.

We thank Drs J. Bahcall and N. Bahcall for making available the results of their positional correlation studies, Dr M. V. Penston

for providing the overlay of Fig. 2 and the Hale Observatories for permission to reproduce the Palomar chart.

Galactic X-ray sources and the ionospheric D region

SEVERAL authors (see refs 1-5 for example) have studied the possible influence of galactic point X-ray sources in the ionospheric D region. The observed variabilities in phase and amplitude of very low frequency (v.l.f.) night-time propagation have been attributed to different ionisation sources, but the relationship between the appearance of strong X-ray sources in the sky and the recorded v.l.f. phase and intensity variations has been emphasised. Particularly important are the effects of Sco X-1, Cen X-2 and Cen X-4.

Ion production rates attributable to galactic point X-ray sources have been evaluated², considering a constant photoionisation equal to $1/0.032 \text{ keV}^{-1}$ and energies of up to 10 keV. These calculations do not include all of the energy ranges available in the measured spectra. Therefore, the results obtained suggest that the contribution of point X-ray sources to the total ion production of the D region is small.

We calculate here theoretical ionisation rates which include energies up to 50 keV, non-constant photoionisation yields⁶ and the latest available measured spectra. The total electron production rate attributable to a celestial X-ray source is given by:

$$Q(z) = \int_{E_0}^{E_{\text{max}}} q(E, z) dE$$

where

$$q(E, z) = I(E, z) \sum_i \gamma_i(E) \sigma_i(E) n_i(z)$$

and

$$I(E, z) = I_0(E) \exp[\sec \theta \sum_i \sigma_i(E) \int_z^{\infty} n_i(z) dz]$$

where, $I_0(E)$ is the intensity of the emitted X rays at the top of the atmosphere; suffix i indicates the neutral constituent species considered (N_2 , O_2 and O); $n_i(z)$ is the number density of neutral atmospheric constituent i at altitude z ; $\sigma_i(E)$ the absorption cross section of neutral atmospheric constituent i for electromagnetic radiation over an energy range E ; and $\gamma(E)$ is the photoionisation yield, that is, the number of electron ion pairs formed per photon with energy E absorbed by a neutral atmospheric constituent i .

Figure 1 shows the ionisation rate attributable to Tau X-1 (ref. 7), Sco X-1 at 0° , 30° and 45° for normal conditions⁸ where $I_0(E) = 110 \exp(E/4.3)$, and for flare conditions⁹ together with the ion production attributable to other minor point X-ray sources in the southern sky¹⁰. It is important to

Fig. 1 Rates of ionisation production from: a, Tau X-1; b, Sco X-1; c, other minor sources in the Southern Hemisphere sky.

note that the profiles shown differ considerably from those given in the publications mentioned.

Figure 2 shows the ionisation rates attributable to major night-time ionisation sources: Lyman β , considering the flux given by Young *et al.*¹¹; scattered Lyman α calculated using the NO density distribution given by Meira¹², and the flux given by Winter *et al.*¹³; cosmic rays¹⁴ and the contribution of a diffuse galactic X-ray background⁶.

The contribution of Sco X-1 to the night-time ion production, is significant compared with the other major night-time sources, but the effect of the minor X-ray sources included can be neglected. Therefore, these results support claims that there is a Scorpius X-1 effect on the v.l.f. signal propagation records.

Fig. 2 Rates of ionisation production from major night-time ionisation sources: a, Lyman- β radiation; b, scattered Lyman- α radiation; c, stellar X-ray sources; d, galactic cosmic rays ($\gamma_m = 0^\circ$); e, galactic cosmic rays ($\gamma_m = 55^\circ$); f, diffuse galactic X-ray background; g, Tau X-1; h, Sco X-1.

Similar conclusions could be drawn for Cen X-2 (ref. 15) and Cen X-4 (ref. 16) since it has been shown that their spectral shape and intensity are comparable with those of Sco X-1.

Geomagnetic effect associated with X-ray flare from Sco X-1

THE effect on the night-time lower ionosphere of X radiation from celestial sources is a topic of some controversy¹⁻⁴. An X-ray flare from Sco X-1 has been shown to have a daytime effect on the ionosphere⁵ and it has also been reported⁶ that celestial X-ray sources have a nocturnal effect on the lower ionosphere in certain conditions. Galactic X-ray ionisation has been shown⁷⁻⁹ to affect night-time geomagnetic field components.

We have examined the possibility that an X-ray flare from Sco X-1, detected in the course of a balloon flight on October 15, 1967 at Mildura (34° 12'S; 142° 6'E)¹⁰, had a daytime geomagnetic effect. We observed a conspicuous perturbation in the form of an increase in the horizontal component of the magnetic field observed at the equatorial station at Kodaikanal (10° 14'N, 77° 28'E).

On October 15, 1967, Sco X-1 flared up at about 0700 UT, reaching a maximum in less than 10 min and then decreasing during the next 20 min (Fig. 1). The perturbation in the horizontal component of the magnetic field started around 0715 UT, and rose to a maximum at 0725 UT (an increase in the *H* component of about 14 γ), about 16 min after the flare had reached a maximum at around 0710 UT. Unfortunately, a small optical solar flare occurred about 15 min before the Sco X-1 flare, during the period 0647-0710 UT, with a maximum at 0650 UT.

In view of this, we have examined the possibility that the observed geomagnetic effect was caused by this solar flare, using the available solar X-ray flux data for this event. The procedure followed is similar to that adopted by Ramanamurthy et al.⁵. Solar X-ray flux data show a small burst in the 8-12 Å band during the period 0640-0713 UT but it is considered unlikely that it produced a solar flare effect (SFE), (geomagnetic crochet) as its amplitude is below the threshold value. Van Allen's data from Explorer 35 show a flare (with a flux enhancement of 2.3) which began at about 0640 UT, reached a maximum at about 0653 UT and ended at about 0730 UT. An earlier study made by us showed that the relaxation time of the SFE (geomagnetic crochet) with reference to the solar X-ray flare (1-20 Å) ranges from -10 to +22 min (with an average value of 4.0 min for the 1-8 Å band and 1.4 min for the 8-20 Å band). Thus, the observed time lag of about 33 min between the solar X-ray flare (2-12 Å) maximum and that of the observed geomagnetic effect is well outside the range of relaxation times for geomagnetic solar flare effects (SFE or crochet events).

The possible daytime geomagnetic effect of Sco X-1 is considered more interesting than the nocturnal effect reported earlier, as during the day the rate of ion production resulting from the Sco X-1 X-ray flux has to compete with the rate resulting from the solar X-ray flux and L_{α} besides that resulting from galactic cosmic rays. An estimation of the production rates

Fig. 1 Kodaikanal, October 15, 1967; temporal variations in: a, the horizontal component, *H* of the magnetic field at Kodaikanal; b, 20-30 keV X-ray counts from Sco XR-1 (ref. 10); c, the field strength (164 kHz) over the Tashkent-Delhi path (after Ramanamurthy et al.⁵); d, the solar X-ray flux 2-12 Å (Van Allen) and 8-12 Å (Teske), (after Ramanamurthy et al.⁵).

attributable to Sco X-1, L_{α} and galactic cosmic rays indicates that the rates of production attributable to the X-ray source are comparable with those attributable to cosmic rays and L_{α} at levels below about 70 km (ref. 5). So the observed geomagnetic effect could be attributable to X-ray flux enhancement (1-20 Å), as during an SFE (crochet) the region of enhanced conductivity lies in the D-region¹¹⁻¹⁴.

A sudden impulse (SI) was reported on October 15, 1967 at 0724 UT from two stations, SO and HL and an SSC was reported from station SU (Solar-Geophysical Data ESSA/NOAA). In view of the circumstantial evidence presented here, however, we do not consider the observed geomagnetic perturbation at Kodaikanal as an SI or an SSC but as a genuine effect of the X-ray flare from Sco X-1.

Ghost echoes on the Earth–Moon path

ON July 7, 1974 while using a Moon Bounce technique on 1,296 MHz I observed the appearance of strange, delayed echoes. My equipment consists of a parabolic antenna 26 feet in diameter with a circularly polarised feed horn driven with 500-W continuous wave from a transmitter. The receiver has a noise figure of 2 dB and a bandpass of 500 cycles and the equipment had a very distinct note because of a spurious frequency near the fundamental; on the Moon–Earth circuit it is very easy to identify this signal because of this unique characteristic. On the day in question a series of dots or a single dash were being reflected back from the Moon after 2.6 s. Suddenly there appeared a second signal delayed by approximately 2 s. This signal had the same characteristics of the Moon Bounce signal except that it was weaker.

At the time of the observations it was afternoon, the Sun was almost due west and the Moon was to the south-west with an altitude of about 30°. Throughout a series of transmissions the returning Moon signal was followed about 2 s later by the delayed ghost signal with the same characteristic note of the transmitter. Unfortunately, I could not record the signals though they continued for 20 min. When I failed to track the Moon with my antenna, the Moon signal would fade but the echo remained at about the same strength.

The following day a severe radio blackout occurred, and lasted for several days, coincidentally with the appearance of a large sunspot. Relating my reception of the ghost echo with this violent solar eruption I suggest that the large streamer of gas from the corona of the Sun produced a highly ionised cloud which reflected the radio signals I had directed towards the Moon. If this streamer approached with a speed of 1,000 km s⁻¹, with a front like a shock wave, it could have acted as a good reflector. The cloud would have been about 800,000 km out in space, as indicated from the delay times of 4–5 s.

²²Na, Ne–E, extinct radioactive anomalies and unsupported ⁴⁰Ar

A NEW picture¹ of the origin of the known extinct radioactivities (¹²⁹I and ²⁴⁴Pu) holds that these radioactive species were precipitated in grains forming in the rapidly cooling ejecta of explosive nucleosynthesis, and that their decay occurred in interstellar grains rather than in the meteorites. If so, our interpretation of extinct radioactivities is enlarged. Their detectability is no longer related to the usual criterion that they live long enough for the meteorites to form, but rather that they live long enough for grains to form in the expanding envelope.

My first point is to interpret ²²Na as a detectable extinct radioactivity. Its half life (2.6 yr) seems long enough for an expanding gas to cool to the point of grain formation. If we take the adiabatic relationship $p/T^3 = \text{constant}$ for purposes of a simple estimate, we find that matter having a density of

10⁴ g cm⁻³ at $T=10^9$ K has a density of 10⁻¹⁴ g cm⁻³ when $T=10^3$ K where grains can form copiously. The observations² of Nova Serpentis 1970 confirm very extensive grain formation in similar circumstances on a time scale of a few days. If the expansion speed of a supernova envelope is 10⁴ km s⁻¹, this drop in density requires about 3 yr. Condensation temperatures may be reached even earlier if the expansion is not adiabatic, but also radiates.

The ejection of ²²Na in large amounts is expected from the helium shells of explosive supernovae³ and from the surface explosions of novae⁴, both at the level 10⁻³ g g⁻¹. I have studied these for their prospects for nuclear gamma-ray astronomy, but since ²²Na may in part be expected to precipitate in grains before it decays, we may also expect the existence of interstellar grains being isotopically rich in ²²Ne in comparison with the Sun. The admixing of these grains without vaporisation into the forming carbonaceous chondrites is a good candidate for the source of the ²²Ne-rich neon component Ne–E, which was discussed by Black⁵, who attributed it to an extrasolar source. It is at least as ²²Ne-rich as ²⁰Ne/²²Ne ≤ 3.4, and could conceivably be pure ²²Ne. The fact that the released gas is purest in Ne–E around 1,000 °C in stepwise heating probably reflects the fact that ²²Ne occupies a refractory ²²Na site in the grains. The absolute amounts of ²²Ne are also relatively constant near 10⁻⁹ cm³ g⁻¹ STP, suggesting uniform sprinkling of presolar grains through C1 chondrites.

The ²²Na yield is more than adequate to account for the Ne–E anomaly. Nucleosynthesis calculations suggest, but do not prove, that the fraction of all ²²Ne that was synthesised as ²²Na, in specific ejecta concentrations near 10⁻³ g g⁻¹ (refs 3, 4), is about 10⁻², which is also about 5 × 10⁻² of the total stable ²³Na abundance. This total nucleosynthesis yield is quite large, and about one-tenth of it is here supposed to be incorporated into grains before the ²²Na decay. I have argued¹ that the fraction f_{Na} of condensed solar system Na that existed as unvaporised presolar grains lies between 10⁻¹ and 10⁻². If these estimates are correct, the concentration of Ne–E potentially available if neon gas were not lost from grains is between 5 × 10⁻⁴ and 5 × 10⁻⁵ of stable Na. That this is many orders of magnitude greater than observed Ne–E concentrations reflects the loss of daughter neon from the hot but unvaporised grains.

A correlation of Ne–E with Na concentration would not necessarily be expected, however, because these same explosively ejected zones are not rich in stable ²³Na. This Ne–E is a component of Ne–A (ref. 5), which shares a “threshold-for-appearance” effect with He–A, which is deficient in ³He in comparison with the solar wind. Component A is interpreted by Black⁵ as a linear combination of E and a component D, which he interprets as a primitive solar wind, before the deuterium has burned to ³He. In the framework of the present discussion, we see that D may also contain the dense gas surrounding the newly formed grains in the expanding supernova. I suggest interpreting E as ²²Ne from ²²Na decay and essentially pure ⁴He from the helium shell in which the ²²Na is synthesised³. Other isotopes of neon, especially ²¹Ne, also exist in the gas, but $(^4\text{He}/\text{Ne})_{\text{gas}} \approx 10^4$ so that ⁴He should be the dominant trapped gas. Only if neon is trapped more efficiently than helium in this environment will the newly synthesised neon gas contribute a component to E as well. Calculations of this neon synthesis have been published^{6,7}. Arnould and Beelen⁷ noted the similarity to Ne–E of special cases of the total gas yield, but the ²²Na interpretation seems more plausible since it is much more easily trapped than neon gas.

Black⁵ also calls attention to the fact that in the C2 chondrite Nagoya the dark gas-rich phases contain 3 times as much ⁴⁰Ar as the light gas-poor phases, although the light phases have a higher fraction of Ne–E in their total neon. Perhaps the explanation is that the dark phases contain a higher fraction of presolar grains. The ⁴⁰K/⁴¹K ratio was initially much higher in nucleosynthesis events, so grains forming there rather than in the solar system would now have more ⁴⁰Ar/⁴¹K. This suggestion is not necessarily inconsistent with the bulk ²⁰Ne/²²Ne

ratios, because the dark gas-rich portions may contain absolutely more Ne-E than the light phases. It has simply been diluted by more captured gas. In any case, it must be pointed out that such grains would seem to have "unsupported ^{40}Ar ". Interstellar grains accreted by the lunar surface, as I have suggested¹ from unsupported fission xenon, would also show unsupported ^{40}Ar . Since unsupported ^{40}Ar has been found in lunar soil⁹, this idea as a partial source should not be overlooked.

The views expressed here suggest many correlations to look for. Calcium should be a rich element for anomalies. The greatest may be at ^{44}Ca , which we⁸ have shown is synthesised as 47-yr ^{44}Ti . Titanium is also refractory, so both elements condense out early, but a $^{44}\text{Ca}/^{40}\text{Ca}$ correlation with Ti/Ca is here predicted in the small scale structure. The heaviest isotopes of Ca are, moreover, probably synthesised¹⁰ in different mass shells from ^{40}Ca , so they may also be expected to show small scale anomalies. Since ^{41}K is synthesised as radioactive ^{41}Ca (ref. 8), small ^{41}K excesses correlated with calcium concentration are predicted. Anomalies due to ^{26}Al should also be interpreted in terms of presolar grains rather than a primordial concentration.

Our calculations⁸ show that ^{53}Cr is synthesised as parent ^{53}Fe , which is arrested at 2×10^6 yr ^{53}Mn . In grain formation, therefore, a substantial part of this yield will chemically correlate with Mn. That is, a correlation of $^{53}\text{Cr}/^{52}\text{Cr}$ with Mn/Cr is predicted. Peculiarities at ^{54}Cr are also expected, in as much as it is synthesised in a separate process¹¹.

Another outstanding candidate is iron: ^{54}Fe is synthesised¹¹ along with $^{56,57}\text{Ni}$, which are themselves held up for months to years before their transmutation to $^{56,57}\text{Fe}$ is complete. Grains forming in this period could show Ni or Co correlated anomalies due to chemical effects. They will also be deficient in ^{56}Fe , which is synthesised elsewhere¹¹. Other possibilities suggest themselves once the key idea is in mind.

Preferential orientation in four C3 chondritic meteorites

It is more than a century since oriented fabrics were first noted in chondrites (see ref. 1), but since then little work has been done on the topic^{2,3}, the most extensive being that by Dodd⁴. He found that most of his H- and L-group chondrites possessed foliation, together with lineation in the most strongly foliated specimens. The preferential orientation of elongated olivine phenocrysts in porphyritic chondrules has also been observed⁵.

A visual examination of the Leoville C3 chondrite disclosed a strong orientation of the long axes of the chondrules. This prompted us to compare the orientation of the long axis of the chondrites in this meteorite with three other Type 3 carbonaceous chondrites: Grosnaja, Coolidge and Vigarano. We were unable to obtain specimens cut with three mutually perpendicular faces, the most desirable configuration for a study of this kind. Our preliminary samples generally possessed only one face cut

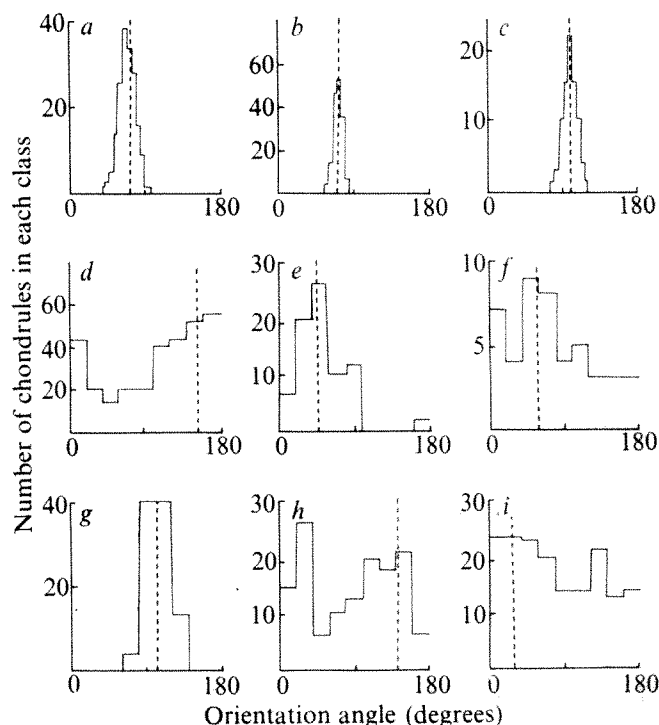

Fig. 1 Histograms of the orientations of the long axes of chondrules in four C3 carbonaceous chondrites. Leoville specimens: a (LU 44484), vector magnitude (V_m) = 94.1%; b (BM 1969, 144), V_m = 98.5%; c (LU 44484), V_m = 95.6%. Three faces of Vigarano specimen (BM 1924, 15); d, V_m = 29.3%; e, V_m = 67.8%; f, V_m = 24.1%. Grosnaja specimen (BM 63624): g, V_m = 86.1%; h, V_m = 14.1%; i, V_m = 11.2%. Marked lines, mean vector directions.

at random, and we may, therefore, have encountered some of the problems outlined by Dodd⁴.

We thus decided to photograph each available face using fine-grained monochrome film, and then to prepare appropriate enlargements. This avoided the problem posed by the removal and transport of actual specimens and facilitated magnification to a suitable size. Individual photographs were mounted on the table of an orientometer designed to allow movement in translation and rotation⁶, and were viewed through a binocular microscope fitted with a line reticule in one eyepiece. Chondrules were aligned with their long axis along this fiducial line, and their nominal orientation was read from the degree scale of the orientometer turntable. Each measured image was marked with a spot of ink to avoid confusion and possible duplication. The measurements are of the double-headed vector type⁷, so only the direction between 0° and 180° was taken.

Chondrule orientations for each specimen were grouped into 5°, 10° or 20° classes according to the number of measurements and their scatter, and the resulting histograms are shown in Fig. 1. The mean vector direction and its magnitude are also shown, complete orientation being expressed as 100% and a random distribution by 0% (ref. 7).

Histograms give a good visual idea of the presence and degree of any orientation and our measurements indicate a high degree of orientation of the long axes of chondrules from all specimens of the Leoville chondrite, in the Grosnaja specimen, and on face b of the Vigarano specimen (Fig. 1 a, b, c, e and g). The other two faces of Vigarano (Fig. 1 d and f) exhibit a much lower degree of chondrule orientation, and the Coolidge specimens (Fig. 1 h and i) show a wide scatter. These qualitative impressions are borne out by the calculated vector magnitude.

From these results it seems that the orientations of the long axes of chondrites are strong in Leoville and Grosnaja chondrites, moderate in one plane of the Vigarano specimen, and very weak or nonexistent in the Coolidge specimens. Dodd⁴ could find no preferred orientation in the last-named

meteorite. The wide range of degrees of orientation between the four C3 chondrites examined also supports Dodd's conclusion⁴ that there is no correlation between orientation and degree of metamorphism.

The identification of the mechanisms which produced asphericity and alignment of the chondrules in some chondrites is not an easy matter. Are these phenomena related to the primary chondrule-forming process, to effects occurring during aggregation, or are they a result of secondary processes in the meteorite parent body? Are the two phenomena related? More data are needed before these questions can be resolved.

For this reason we are at present examining the orientations of the long axes of chondrules in more detail, along with such factors as shape and size distribution, density, friability, and so on. It is hoped that these studies will enable us to draw conclusions concerning the formation of chondrules and the genesis of meteorites.

Possible ozone depletions following nuclear explosions

HAMPSON¹ has commented on the possible destruction of the Earth's ozone shield by nitric oxide generated during nuclear explosions in the atmosphere. He suggested that if such an ozone decrease were large enough and lasted long enough, it might have disastrous effects on the biosphere. Here, we assess quantitatively Hampson's suggestion.

We have considered only nuclear detonations occurring near the ground, with the NO formed and carried into the stratosphere by rising fireballs. High altitude bursts would probably be much lower in total yield; moreover, NO injected above the stratosphere has a shorter photochemical lifetime and is less effective in removing ozone than is NO deposited in the stratosphere. To calculate the quantity and distribution of NO in the atmosphere after a series of large nuclear explosions, we have assumed that each megaton of nuclear yield generates 10^{32} molecules of NO, an average value between upper and lower limits^{2,3}. We have assumed that the NO is uniformly mixed in the nuclear cloud at stabilisation, when it has a spheroidal shape and lower and upper altitudes given by the empirical curves of Peterson⁴ for 30° to 90° latitudes.

For the total yield we have chosen two values: 5,000 Mton (case 1), as suggested by Hampson¹, and twice that, 10,000 Mton (case 2), in order to assess a more severe case. In both cases the total yield was provided equally by 1 Mton and 5 Mton devices. This choice is approximately consistent with published tabulations of strategic nuclear armaments⁵ delivered by missile. To determine the sensitivity of the results to the individual yields, an additional case consisting of 5,000 Mton provided equally by 1 Mton and 3 Mton devices, has also been treated. The injected NO is assumed to be uniformly distributed either between 30° and 70°N, or over the entire Northern Hemisphere. The latter

Fig. 1 Initial concentrations of nitric oxide generated by nuclear explosions for total yields of: a, 5,000 Mton produced equally by 1 and 5 Mton devices; b, 10,000 Mton produced equally by 1 and 5 Mton devices; c, 5,000 Mton provided equally by 1 and 3 Mton devices. The NO molecules are assumed to be uniformly spread over: *, zone between 30° and 70°N; †, the Northern Hemisphere. Each circle point represents an average concentration for a 2-km vertical interval (the model grid spacing) centred at that altitude; that is, it is an average concentration in each 2-km segment.

case is included because hemispherical dispersion can occur in a time (several months) which is short compared with the stratospheric residence time of the NO (several years). The 'initial' NO concentrations for each case are shown as functions of altitude in Fig. 1.

If the nuclear bursts actually were confined between 75°–125°W and 25°–75°E, corresponding roughly to the geographical boundaries of the USA and the populated USSR, it would take about as long for the NO to spread uniformly over the area between 30° and 70°N (ref. 6), as it would take for the ozone column density to reach a minimum (about 2 months). Accordingly, our calculations using longitudinally averaged NO concentrations are only estimates of the average ozone reductions to be expected. A higher initial concentration of the NO_x generated by fireballs in certain geographical regions ensures that the ozone reduction will be somewhat larger in those areas.

Fig. 2 Depletion of the total ozone column as a function of time after a series of large nuclear explosions for cases described in Fig. 1.

The depletion of ozone and atomic oxygen by catalytic reaction with nitrogen oxides produced by nuclear explosions ($O_3 + NO \rightarrow O_2 + NO_2$; $O + NO_2 \rightarrow O_2 + NO$) was assessed using a one-dimensional numerical model of stratospheric and mesospheric constituents that includes 150 photochemical reactions (see ref. 7). The model predicts the concentrations of 46 chemical constituents; only the species O, O(¹D), O₃, OH, HO₂, NO, NO₂ and HNO₃ need to be considered here. The vertical transport of stratospheric gases is represented by an eddy diffusion process; we have selected a diffusion coefficient⁸ which reproduces the vertical distribution of methane at altitudes above 30 km and also gives the proper stratospheric residence times for radioactive tracers (H. S. Johnston, P. Kattenhorn, and G. Whitten, unpublished). This model, however, has a tropopause level at an altitude of 16 km, which is appropriate only for low latitudes; between 30° and 70° the average tropopause is near 11 km. Accordingly, we have shifted the Wofsy and McElroy⁸ diffusivity curve downward by 5 km. The predicted ozone reductions are, of course, sensitive to the eddy diffusivity profile used. In view of the constraints placed on vertical turbulent transport rates by the tracer data, we believe that uncertainties in the calculated ozone depletions resulting from uncertainties in the eddy diffusion coefficients are much less than a factor of two, and are probably not greater than 25%. Our calculations were performed with the Sun at a fixed elevation of 45°. It is valid⁹ to assume a fixed rather than a diurnally varying solar zenith angle when predicting the effects on ozone of artificially injected NO_x.

Figure 2 shows our computed ozone column depletions as a function of time after a large-scale nuclear detonation for combinations of yields and subsequent horizontal spreading. In cases *a* and *b* the peak ozone reductions occur after about 2 months, with large depletions persisting for several years. When the lower weapon yields of 1 Mton and 3 Mton are assumed (case *c*), the NO is injected lower in the stratosphere (see Fig. 1) and our results show slightly smaller ozone reductions for the same total yield as in case *a*, and about twice as long a delay to the peak ozone reduction. The *e*-folding time for ozone recovery is about 3 yr in our model, reflecting the slow transfer of NO_x compounds from the stratosphere to the troposphere by eddy diffusion. After about a year the NO_x should be spread fairly widely throughout the northern hemisphere⁶, thus reducing its concentration to about half the value it would have had were it still confined to the 30°–70°N zone. Comparison of the *a*[†], *b*[†] and *c*[†] curves in Fig. 2 with the corresponding * curves shows that this spreading decreases the ozone reduction by about 20–30%. In the former cases, however, the ozone reduction occurs over the entire Northern Hemisphere, not just in the zone between 30° and 70°N.

Figure 3 shows the post-detonation variation of the ozone concentrations at several altitudes for case *b** in Fig. 7; that is, NO produced by 10,000 Mton distributed between 30° and 70°N. Below the tropopause (~11 km altitude), excess NO_x is so quickly removed by rainout, and its catalytic reaction cycle with ozone is so slow because of low atomic oxygen concentrations, that there is little ozone reduction. In the stratosphere up to about 22 km, the peak ozone reduction occurs more quickly with increasing height as a consequence of the increasing abundance of O. Most of the NO_x above 22 km has been transported upwards by diffusion from lower altitudes, so the peak ozone reduction occurs later for higher altitudes, reflecting the time required for upward transport of NO by eddy diffusion. Eventually, all of the excess stratospheric NO_x is transported either downward into the troposphere where it can be washed from the air by rainfall or upwards into the mesosphere where it can be photolysed into N and O and destroyed by the subsequent reaction $N + NO \rightarrow N_2 + O$.

Our calculated ozone depletions are only estimates because of the expected inhomogeneous distribution of NO produced

Fig. 3 Variations of the ozone concentrations over time at several altitudes for case *b** in Fig. 1. (10,000 Mton zonally distributed): *a*, 10 km altitude; *b*, 16 km altitude; *c*, 26 km altitude; *d*, 36 km altitude; *e*, 46 km altitude.

by nuclear explosion, because of uncertainties in the total amount of NO generated (perhaps a factor of 2) and its initial altitude distribution, and because of probable substantial changes in stratospheric circulation caused by very large ozone depletions. Moreover, our computations apply to mid-latitude conditions, that is, somewhere between 30° and 70°N. For more accurate calculations, a photochemical model with multidimensional transport including thermally-driven winds is required. We do not, however, expect the results from such a study to differ markedly from those reported here, and we therefore conclude that Hampson's concern is well founded.

Trapa natans in the British Flandrian

POLLEN of *Trapa natans* L. the water chestnut, has been found in two Flandrian (Holocene) deposits at Skipsea, North Humberside, providing the first *in situ* Flandrian records of this species in Britain. The occurrence, followed by the extinction, of *T. natans* in Scandinavia has been regarded as evidence of a 'climatic optimum' when summer temperatures were at least 2 °C higher than at the present day¹⁻⁴. The new British data may indicate similar conditions but could also record human activity, in which case it would not be necessary to invoke climatic change.

We studied two former meres occupying depressions on the surface of the Devensian (Weichsel) till. The pollen was

Fig. 1 Pollen grains of *Trapa natans* L. a, b, Reference pollen; c, fossil grain from 2.75 m, Skipsea Bail Mere; d, fossil grain from 2.87 m, Skipsea Low Mere.

found in the fine detritus mud of a 5.50-m core from the site of the former Skipsea Low Mere⁵ (os ref.: TA 155563) at Skipsea, near Hornsea, North Humberside. The total number of *Trapa* grains seen in pollen preparations of samples taken at 0.25 m intervals is shown in Table 1.

The pollen was also present in fine detritus mud of a 4.00-m core from the site of Skipsea Bail Mere⁵ (os ref.: TA 162552) nearby. Examination of prepared slides revealed single grains at 2.75 m, 2.90 m, and 3.25 m, but not in intermediate samples.

The pollen was determined as *Trapa* by comparison first with drawings⁶ and photographs⁷, and, subsequently, with reference material (Fig. 1). *T. natans* is the only species of Trapaceae found at present in western Europe.

There are at least four possible explanations of the find: laboratory contamination, derivation from interglacial deposits, introduction by birds, and actual occurrence of the

Table 1 Total number of *Trapa* grains seen in complete scanning of pollen preparations 0.25 m apart in a core from Skipsea Low Mere

Depth	Number of grains
2.12 m and above	0
2.37 m	1
2.62 m	2
2.87 m	12
3.12 m	1
3.37 m and below	0

species at the two meres in the Flandrian. Contamination seems very unlikely, since no specimen or sample of *T. natans* or of any deposit known to contain it had ever entered our laboratory previously. It is certainly possible that the grains are derived (indeed one specimen is somewhat eroded); for that to be correct, however, requires that the grains were derived twice: first from an interglacial deposit into the Devensian till which surrounds the meres, and then into the mere deposits. The samples contained no other pollen of types which are necessarily derived, nor did they have the appreciable content of mineral matter which could be expected if derivation from till had occurred. Transport of pollen by birds is possible. Seeds and fruits adhere to birds⁸, and pollen may travel in the same way. The nearby Hornsea Mere is an important staging post for waders migrating from Scandinavia (J. E. S. Walker, personal communication) at a time when *T. natans* is flowering (June–September³). Carriage by birds cannot, therefore, be excluded, but should be considered as a remote possibility in view of the regular appearance of the pollen at several stratigraphical levels. The presence of *Trapa* pollen probably indicates that the taxon was living at the site⁹.

The single previous record from the British Flandrian¹⁰ is of a fossil fruit found floating in a brackish loch in the Outer Hebrides. Doubt has been cast on this record⁴ because of the general unlikelihood that the species would occur in so oceanic an environment; in addition the fruit had peat (apparently of the *Sphagnum-Calluna* type) adhering to it, suggesting a bog habitat, whereas *T. natans* is a floating aquatic. Those objections do not, however, apply to the records reported here: North Humberside is not particularly oceanic and the pollen was found in fine detritus mud, representing an environment in which floating aquatics could have existed. The new records should be accepted, provisionally at least.

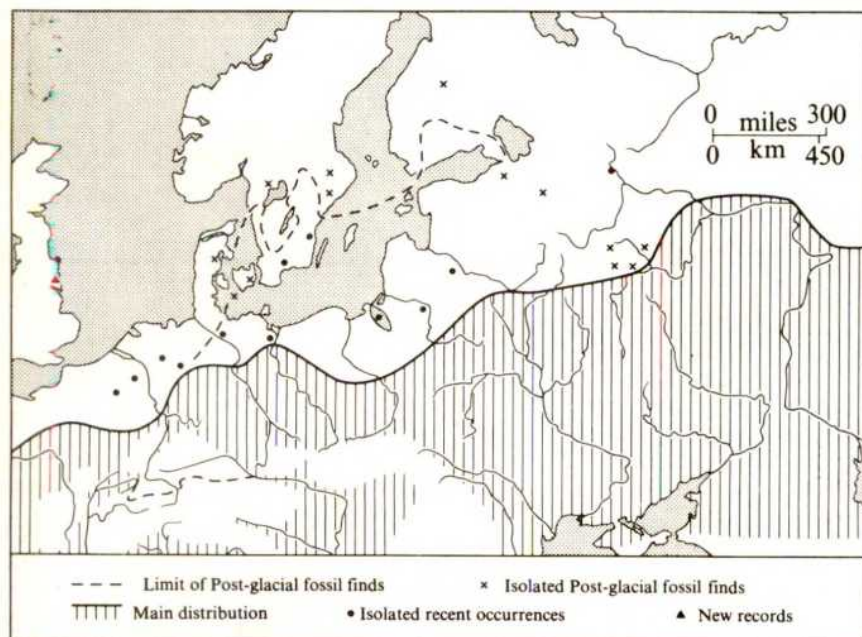

Fig. 2 Distribution of *Trapa natans* (partly after ref. 3).

A pollen and spore count from the main *Trapa* horizon, 2.87 m deep at Skipsea Low Mere, gave the results shown in Table 2.

Outline pollen diagrams showed that the other samples containing *Trapa* from the two meres give similar spectra. These results suggested that *T. natans* was growing in North Humberside after the decline of *Ulmus* but before the main lowland forest clearances (that is, about 2500–500 BC, the period of Bronze Age cultures in Britain). That is the time during which *T. natans* attained its maximum northward extension in Europe, reaching Finland and southern Sweden (Fig. 2)^{1,2}. The arrival of *Trapa* in Northern Europe is usually attributed to ordinary, if rather slow, migration in response to the warm, postglacial climate, although cultivation by man has also been suggested.

Table 2 Pollen and spore count from the main *Trapa* horizon, 2.87 m deep at Skipsea Low Mere

<i>Pinus</i>	1	<i>Corylus</i>	60	<i>Sparganium</i>	2
<i>Ulmus</i>	5	Gramineae	3	<i>Trapa</i>	1

<i>Alnus</i>	85	<i>Solanum</i>	1	Deteriorated grains	4
<i>Fraxinus</i>	8	<i>Nuphar</i>	1		
					Total pollen and spores 255

Suggested causes of the decline of *Trapa* include³ climatic deterioration, a decline in the trophic status of fresh waters, the extinction of beavers, the collection for food by man, the cessation of cultivation as a food plant, disease, and degeneration caused by inbreeding. Most authors^{1–4} prefer a climatic explanation and correlate the decline with the aftermath of the 'climatic optimum' when summers were at least 2 °C warmer than at present. The new records could be used to support this figure.

Explanations relating to man, however, deserve re-examination in the context of the new records. Water chestnuts have been an important source of food in Europe and elsewhere⁵. It is to be expected that a species on the edge of its range will be unusually sensitive to the depredations of man. The activity of a late Bronze Age culture in the area is confirmed by the presence of a substantial lake settlement in Skipsea Low Mere and another in the marshy area between Skipsea Low Mere and Skipsea Bail Mere¹¹. It seems likely that people living there would have taken advantage of this readily available food supply, and may thereby have caused its extinction. Alternatively, man could have introduced and cultivated water chestnuts. That would explain their arrival, and their extinction may have coincided with the decline of late Bronze Age culture.

We thank Drs G. C. S. Clarke, L. F. Penny, and D. Turner, R. H. Watson, C. W. Warkup and the Hull University second year palynology class, 1974, for their help.

A new method of measuring the hydrogen bond stretching frequency ν_{σ} of a complex in solution

THERE is no agreed explanation of the broadening of the infrared absorption bands associated with the $\nu_{\sigma}(\text{XH})$ stretching mode of a hydrogen-bonded complex $\text{XH}\cdots\text{Y}$ in solution (see ref. 1). There is, however, a growing body of evidence to suggest that the distinctive appearance of these bands can be understood in terms of the anharmonic coupling of $\nu_{\sigma}(\text{XH})$ and $\nu_{\sigma}(\text{XH}\cdots\text{Y})$ modes^{2,3}, provided it is recognised that the phase coherence of the $\nu_{\sigma}(\text{XH}\cdots\text{Y})$ mode is rapidly lost owing to the strong interaction between the complex and the solvent⁴. The implication of this proviso is that the $\nu_{\sigma}(\text{XH}\cdots\text{Y})$ motion should be regarded as an oscillatory stochastic process rather than the oscillation of a conservative system.

A model developed by one of us (G.N.R., unpublished), which assumes an explicit form for the anharmonic coupling between the $\nu_{\sigma}(\text{XH})$ and $\nu_{\sigma}(\text{XH}\cdots\text{Y})$ modes and invokes the Ornstein–Uhlenbeck stochastic process to represent the hydrogen bond stretching vibration, allows a simple expression for the molecular dipole moment autocorrelation function to be obtained. This theoretical autocorrelation function depends on three parameters: (1) a mode-mode coupling constant; (2) a viscous damping coefficient, representing the effect of the solvent on the $\nu_{\sigma}(\text{XH}\cdots\text{Y})$ mode, and (3) the angular frequency of the hydrogen bond stretching vibration. By Fourier transformation of digitally recorded infrared spectra we have obtained experimental dipole moment autocorrelation functions for the phenol–acetonitrile complex in solution in carbon tetrachloride and for a number of other systems. Using the method of least squares we have been able to estimate numerical values and standard deviations for the three parameters of the model in each case. In particular, we have been able to measure the hydrogen bond stretching frequency with an accuracy of about 10%.

We believe that this provides the first absolutely conclusive evidence that the $\nu_{\sigma}(\text{XH})$ band profiles (Fig. 1) of hydrogen-bonded species in solution are indeed composite. Furthermore, our method of analysis provides a means of measuring the $\nu_{\sigma}(\text{XH}\cdots\text{Y})$ frequency in cases where the structure in the 3,000 cm^{-1} region of the spectrum is impossible to resolve visually and the far infrared spectrum cannot be recorded.

The theoretical result which is fundamental to the analysis is obtained by requiring that the displacement coordinate r_2 of the $\nu_{\sigma}(\text{XH}\cdots\text{Y})$ mode should obey the Langevin equation

$$\ddot{r}_2 + \beta \dot{r}_2 + \omega_2^2 r_2 = F(t) \quad (1)$$

If the random force $F(t)$ acting on the complex is supposed to be a Gaussian random variable with an infinitesimal correlation time, $r_2(t)$ is a representation of the Ornstein–Uhlenbeck stochastic process, the mathematical properties of which are well understood⁵. By assuming a coupling term in the molecular hamiltonian of the form $K_{112} r_1^2 r_2$ and treating the $\nu_{\sigma}(\text{XH})$ vibration as a quantum mechanical oscillator coupled to a classical stochastic oscillator, it is easy to obtain the dipole moment autocorrelation function

$$\Phi(t) = \exp \left\{ -i\omega_1 t - a^2 \langle r_2^2 \rangle \right. \\ \left. \times \int_0^t (t-x) e^{-\beta x/2} [\cos \tilde{\omega}_2 x + \frac{\beta}{2\tilde{\omega}_2} \sin \tilde{\omega}_2 x] dx \right\} \quad (2)$$

where $\hbar\omega_1$ is the $\nu_{\sigma}(\text{XH})$ energy quantum, $a = K_{112}/m_1\omega_1$, and $\tilde{\omega}_2 = (\omega_2^2 - \beta^2/4)^{1/2}$ in the underdamped case. A similar, but aperiodic, result holds in the overdamped case where $\beta > 2\omega_2$. It is worth noticing that β is determined⁶ by the variance of the

Fig. 1 Comparison of observed ν_s band profile (x) with those of pure Gaussian (\uparrow) and pure Lorentzian (\blacklozenge) bands for phenol-acetonitrile in carbon tetrachloride

random force $F(t)$. A complete derivation of equation (2), indicating the limits of its applicability, is being prepared for publication elsewhere.

For small t this correlation function behaves as

$$|\varphi(t)| = \exp(-\frac{1}{2}\Delta^2 t^2) \quad (3)$$

and for large t it has the asymptotic form

$$|\varphi(t)| \sim C \exp(-\Delta^2 \tau_c t) \quad (4)$$

where the amplitude of modulation Δ and the correlation time τ_c of the $\nu_s(\text{XH}\cdots\text{Y})$ vibration are given by

$$\Delta = a\langle r_2^{-2} \rangle^{1/2} \quad (5)$$

and φ

$$\tau_c = \beta/\omega_2^2 \quad (6)$$

According to Kubo's general theory of frequency modulation by a Gaussian random process⁶, the former expression for $|\varphi(t)|$ is a good approximation for all times if $\tau_c \Delta \gg 1$, the latter if $\tau_c \Delta \ll 1$. In these limiting cases of slow and rapid modulation the spectral profiles are Gaussian and Lorentzian respectively. Published theoretical work on the band shapes of hydrogen-bonded species in solution has either assumed the extreme slow modulation limit⁴ or has attempted to interpolate between the two limiting cases⁷.

The experimental autocorrelation function for the phenol-acetonitrile complex (Fig. 2) shows clearly that neither limiting case is strictly applicable. Since the $\nu_s(\text{XH})$ band in monomeric phenol is close to Lorentzian in form, it seems likely that quite different mechanisms are responsible for the band shapes of the monomer and the complex. This provides indirect support for the view that the coupling of internal modes of the complex influences its spectrum, which is the basic assumption of the present model. Local field effects may well be of some importance⁸, but are not considered here.

Fitting the experimental autocorrelation function to expression (2) above, using the nonlinear least-squares method of Marquardt⁹ as modified by Fletcher and Powell^{10,11}, we obtain the following estimates of the parameters for phenol-acetonitrile in solution in carbon tetrachloride at 22.5 °C:

$$\Delta = (14.8 \pm 0.2) \times 10^{12} \text{ s}^{-1}$$

$$\Delta^2 \tau_c = (11.9 \pm 0.4) \times 10^{12} \text{ s}^{-1}$$

and

$$\bar{\nu}_2 = 120 \pm 12 \text{ cm}^{-1}$$

$$\text{where } \bar{\nu}_2 = \omega_2/2\pi c$$

It follows that $\tau_c \Delta = 0.8$ and $\beta/2\omega_2 = 0.6$. We observe that $\tau_c \Delta$ is close to unity, which confirms that neither the slow nor the rapid modulation limiting approximation is satisfactory.

Although the $\nu_s(\text{XH}\cdots\text{Y})$ motion is underdamped, it is not far from being critically damped, and this suggests that the far infrared spectrum of the complex in solution should be extremely broad. We have failed so far to observe the far infrared spectrum.

It should be particularly noted that we are able to calculate the standard deviation of our measurement of the hydrogen bond stretching frequency. Although we cannot exclude the

Fig. 2 Comparison of observed dipole correlation functions obtained by transformation of the spectral bands shown in Fig. 1.

possibility of systematic errors (arising from the crudity of the theoretical result on which the analysis is based, or even from bias in our sampling procedure) we must point out that no other method of measuring the $\nu_s(\text{XH}\cdots\text{Y})$ frequency allows a reliable estimate of the errors of observation to be made. We believe therefore that our procedure must be regarded—by default—as the most trustworthy method yet devised for measuring the hydrogen bond stretching frequency of a complex in solution. It must be admitted, however, that the model makes no provision for any spectral broadening produced by local field effects or by the involvement of rotational and bending degrees of freedom, and that these questions need urgent attention.

We have not attempted in this preliminary report to discuss the temperature dependence of the position of the $\nu_s(\text{XH})$ band centre, although it is relatively straightforward to do so by introducing a further coupling term in the model hamiltonian.

There are several ways in which the model may be tested more stringently. First, the modulation amplitude parameter Δ of equation (5) should decrease by a factor of nearly $2^{-1/2}$ on deuteration. This we have verified for the phenol-dioxan system. Secondly, changing the solvent or varying the amount of excess base (which we have found to produce distinct spectral changes, thus confirming previous work on similar systems^{12,13}) should affect the viscous damping parameter β and thus affect the correlation time τ_c of equation (6).

Finally, changes in temperature should affect both Δ and β . The former, being proportional to the root mean square amplitude of a quantum mechanical harmonic oscillator, should vary as $[\coth(\hbar\omega_s/2kT)]^{1/2}$, or as $T^{1/2}$ at sufficiently high temperatures. The latter, being a viscosity coefficient, is expected to decrease exponentially with increasing temperature. Further experimental work on these problems is in progress and will be reported at a later date, together with a more detailed analysis of experimental errors.

We thank Professor S. Bratos for discussions, the South African Council for Scientific and Industrial Research for financial support and the Royal Society for an equipment grant. Mr S. Marlow of AERE Harwell provided a copy of the Harwell Subroutine Library, containing a Fortran version of Marquardt's algorithm.

Effect of noise on shock-elicited aggression in rats

ONLY a limited number of experiments have been designed to evaluate the effects of noise on aggression. As animal models of aggression are amenable to pharmacological and physiological analysis we have investigated the effect of noise on aggression in rats and have found an interesting non-monotonic relationship, with an increase in aggression at moderate noise levels but a decrease at high levels. The aggressive behaviour chosen for

Fig. 1 Mean percentage fighting \pm s.e.m. at each of four shock intensities, 10 shocks each at 1, 1.5, 2 and 2.5 mA when the background noise was either 75 dB (solid) or 55 dB (dotted) for eight pairs of rats. Duration of shock 1 s, 15 s between shocks, 2 min between each shock intensity. Sprague-Dawley male rats 300–350 g, $30 \times 28 \times 24$ cm Plexiglas test cage in sound-attenuated chamber. White noise intensity measured by General Radio Model 1551-C sound level meter. The pairs of rats placed in test chamber were not previously housed together. Half the pairs received 75 dB first, half 55 dB. Three days later pairs retested in reverse conditions.

the present experiments was shock-elicited aggression in the rat. Two rats were paired in a small enclosure and subjected to a series of footshocks which elicit fighting, depending on the intensity, frequency and duration of electric shock^{1,2}. This is a well documented and highly reliable form of aggressive behaviour that is usually considered a form of irritable aggression³.

The results of Experiment 1 are shown in Fig. 1, which plots mean percentage fighting $[(\text{observed fights}/\text{total possible fights}) \times 100]$ at each of four shock intensities when the background noise level was either 75 or 55 dB. The number of fights increased as the intensity of shock increased but at each shock intensity the number of fights was greater in the 75 dB compared with the 55 dB condition ($F(\text{shock intensity}) = 60.9$; d.f. = 3/21; $P < 0.001$; $F(\text{noise}) = 23.46$; d.f. = 1/7; $P < 0.001$; $F(\text{interaction}) = 1.22$; d.f. = 3/21; $P > 0.10$). This experiment indicates therefore that footshock-elicited aggression was increased by raising the level of background noise.

It is possible that noise increases shock-elicited aggression by increasing arousal. Many arousal mechanisms exhibit non-monotonic relationships to stimulus intensity where the behavioural effect is greatest at intermediate levels of stimulus

intensity, but less at low or high levels of stimulus intensity. For example, the relationship between the startle response and background noise is a non-monotonic one^{4,5}. Both the startle response and shock-elicited aggression may be considered to reflect types of irritability which might be influenced by shifts in arousal. As background noise may be an effective means of manipulating arousal, it was of interest to determine whether shock-elicited aggression would also bear a non-monotonic relationship to the level of background noise. Experiment 2 was designed to evaluate this possibility.

Figure 2 shows the mean percent of fights across the 30 shocks at each of three levels of background noise and indicates that the relationship between this measure of aggression and noise level was a non-monotonic one ($F(\text{quad}) = 110.37$; d.f. = 1/16; $P < 0.001$). Thus, there was an increase in aggression when the noise level was raised from 55 to 75 dB ($t = 3.40$; d.f. = 8; $P < 0.001$), but a decrease in aggression when noise level was raised to 90 dB ($t = 5.21$; d.f. = 8; $P < 0.001$). In addition, there was even less fighting at the high intensity of background noise than at the low intensity ($t = 2.11$; d.f. = 8; $P < 0.05$).

Experiment 3 was designed to evaluate whether the length of exposure to noise before testing would influence subsequent aggression. Different groups ($n = 9$) were exposed to either 55 or 75 dB noise for either 1, 5 or 15 min. After pre-exposure, a series of 30, 2 mA shocks were presented at the same noise level used during pre-exposure. The results indicated that although there were highly significant increases in the number of fights during 75 compared with 55 dB noise conditions ($P < 0.001$ in each group) there was no significant effect of varying the length of pre-exposure to noise before testing.

Experiment 4 was designed to evaluate how long the increase in aggression that occurred when testing was carried out at the 75 dB noise level would continue, once that noise was turned down. Nine pairs of rats were each given a series of 40, 2-mA shocks at a 15-s intershock interval 5 min after being placed in the test cage. For three pairs the background noise was 75 dB throughout, for three other pairs it was 55 dB throughout. For

the last three pairs the noise was 75 dB for the first 5 min but 55 dB thereafter. The various pairs were then tested in the other two conditions 3 and 6 d later using a 3×3 latin square to determine the order of testing.

The following results were obtained. When rats were exposed to 75 dB throughout the test period the amount of fighting increased to a maximum level in 2.5 min and remained at this level thereafter. Rats exposed to the 75 dB noise level which was then reduced to 55 dB also quickly increased their frequency of fighting to a peak at 2.5 min. Thereafter the frequency of fighting rapidly declined, so that after approximately 3.75 min it was equal to that of rats exposed to 55 dB throughout. The last two experiments indicate therefore that the effect of noise on shock-elicited aggression is most dependent on the level of noise present during testing where the effect develops and decays very rapidly.

The present series of experiments demonstrate that noise can influence shock-elicited aggressive behaviour. The precise mechanism which mediates this effect remains to be investigated. One possibility might be that noise increases arousal. Increasing arousal by electrical stimulation of the reticular formation⁶ or by amphetamine⁷ has been shown to facilitate aggressive behaviour in the cat. Moreover, the relationship between arousal and behaviour often seems to follow an inverted U function⁸ where increases in arousal at first increase the frequency and/or intensity of behaviour but further increases in arousal actually decrease the same behaviour.

The 55 dB point represents baseline noise level with the noise generator turned completely off.

Strain differences in maze-learning ability of *Drosophila melanogaster*

If it could be demonstrated that *Drosophila* are able to learn, then our extensive knowledge of the genetics of this dipteran could be applied to understanding the biological bases of learning. Reports of learning in *Drosophila*¹⁻³ sometimes involve changes in orientation as the result of aversive stimulation, for example, electric shock. The use of these stimuli can bring additional problems such as conditioned inhibition where the animals cease responding altogether⁴. The present paper is the first report of work on a unique learning situation which is based on the well-known mazes used to study taxes in *Drosophila*⁵ and involves no aversive stimulation.

We have used modifications of 11-unit mazes (Fig. 1), where flies are allowed 24 h to travel from the starting tube to the collection tubes, making 10 right-left choices at junctions connected by one-way cones. Gravitational and extraneous light cues were eliminated by mounting each maze horizontally, with an opaque base, sides and top. The internal parts of the maze were of clear Perspex which allowed the flies to be attracted through the maze by phototaxis, the light source being a 10 W fluorescent lamp, the width of the maze, shining

Fig. 1 Schematic drawing of the maze. Dashed lines represent the possible pathways in the modified maze, where the other alternatives are blocked off. Dimensions: 62×49 cm. Small drawing shows a typical junction with the interconnecting one-way cones.

from behind the collection tubes. In such a maze, one does not know the sequence of turns made by the flies. If the number of choices is reduced from 10 to 3, however, by blocking off certain junctions of the maze (Fig. 1), the flies are limited to eight alternative pathways, corresponding to the eight collection tubes, tubes +3, 0 and -3 no longer being used.

This modified maze was used to study the sequence of choices in five replicates of each of 10 strains of *D. melanogaster*, LM20-29, derived from single inseminated females captured 9 yr previously at Leslie Manor in Victoria Australia and inbred mainly by single-pair matings since that time. Genetic variation for other traits, such as mating speed, chaetae number and desiccation resistance exists between these strains⁶. Because locomotor activity changes in young flies⁷, all testing was carried out 3 d after eclosion: 100 males and 100 females of the same strain were put in the starting tube (diameter 2 cm, depth 1 cm), providing sufficient crowding to induce the flies to enter the maze. Compared with other experiments where only 50 (ref. 2) or 60% (ref. 8) of the flies completed the task in the allotted time, an average $92.1 \pm 7.8\%$ of these 200 flies reached the collection tubes (10 × 2.5 cm culture vials) at the other end of the maze.

Unlike conventional maze studies where subjects are run through the same maze several times, the flies here were only

tested once. The index of learning involved comparing the probabilities of going left or right at the start of the maze and the probabilities of repeating this response at the second choice-point indicated in Fig. 1, termed PL, PR, PLL and PRR, respectively. Between these two choices the flies were forced to make six turns, to the left in the case of those initially turning left and to the right for those initially going right. If the behaviour of the flies is unaffected by the six forced turns, then the values of PLL and PRR should be similar to those of PL and PR, any change being denoted by $CL = PLL - PL$ and $CR = PRR - PR$. Significant values of CL and CR indicate that when presented with a choice, flies are more likely to continue the sequence of turns they were forced to adopt for the previous six turns. That is, they learn that this sequence of turns enables them to proceed through the maze towards the light, which presumably also acts as an orientational cue in their turning.

All the necessary statistics can be calculated from the distribution of flies in the eight collection tubes. PL is the proportion out of all the flies in these eight tubes that are in the four tubes on the left side and that therefore must initially have turned left. PLL is calculated as the proportion out of the flies from the four left-side tubes that are in the two furthest left tubes (+5 and +4). PR and PRR are calculated similarly for those flies initially turning right.

Analyses of variance (Table 1) revealed significant differences between the strains in PL, the initial tendency to go left. Moreover, as found in earlier work⁶, flies are initially more likely to turn left than right (overall mean PL = 0.5446). Such a turning bias has been observed in other arthropods⁹ and cannot simply be attributed here to asymmetry of the maze, as any such influences would be the same for each strain (the testing of the five trials of each strain were randomised between three identical mazes, each completely separated by matt-white partitions from the other mazes)—that is, asymmetry alone does not explain the observed differences in PL among the strains.

From the significant strain differences in CL and CR (Table 1), we see that after six forced turns to the left or right, the flies of some strains are more likely to choose to continue turning this way. The overall mean values for CL and CR of 0.1644 and 0.2655 respectively indicate that the increase in this probability is considerably less for left- than for right-turning, although the latter was initially the less frequent choice.

Flies that learn follow the outer walls of the maze, and it is necessary to consider alternative factors to learning that could lead to flies behaving in this way. One crucial experiment demonstrates that such alternatives could not contribute to the strain differences in learning.

Table 1 Values of PL, CL and CR for the ten inbred strains, and analyses of variance

Strain			
× sex	9	0.92	0.39
Between replicates	80	1.60	0.65

PL is the initial probability of turning left, CL the change in this probability after an initial left choice and six forced turns and CR the corresponding change in the probability of going right after an initial right turn. Means s.e. of five runs of 200 flies (100 of each sex). The values of CL and CR which differ significantly from zero are indicated thus (d.f. = 4 in all cases), * $P < 0.05$; † $P < 0.01$; ‡ $P < 0.001$.

Mean squares for analyses of variance have been multiplied by 100. The between-replicates variance could be used as an error variance only for PL, as the corresponding variances for CL and CR differed significantly between the strains, those with low means having larger variances, presumably because their choices were more random. Transformations of the data were attempted but did not reduce heterogeneity of the variances.

Five sets of 200 flies (100 of each sex) of strains LM20, 26, 27 and 28—which vary from both CL and CR being significant to neither being significant (Table 1)—were tested in the normal 11-unit maze with no passages blocked off and where flies thus were not forced to repeat a sequence of turns. Otherwise the mazes were identical. The mean percentages \pm s.e. of flies ending up in one or another of the outermost tubes (that is, +5, +4, -4, -5) were, for each of the above strains, 35.6 ± 3.9 , 42.8 ± 4.7 , 21.4 ± 1.9 and 30.8 ± 1.5 , respectively. Although these results do show that some strains are more likely than others to follow the outside wall and so end up in the end tubes, these strain differences bear no relationship to the differences in CL and CR in the eight-unit maze—that is, large values of CL and CR in strains like LM20 cannot simply be the result of flies following the maze walls without learning.

That other strains like LM28 follow the walls to the same extent as LM20 in this maze but show no significant CL or CR in the eight-unit maze eliminates explanations of the learning by factors such as a light gradient, where flies merely follow the outer walls because of cues provided by light getting through the black Perspex baffles at each side of the maze or shining from the maze end, but being reflected differentially from the outer and inner maze surfaces. Although they are already excluded by this 11-unit maze experiment, there is some more specific evidence to eliminate other possible alternatives to learning for the eight-unit maze performance:

Stampede effect, where flies follow each other in groups³. At 2 and 4 h after starting the 200 flies in each maze, the means \pm s.d. of the number of flies having reached the collection tubes were 49.5 ± 34.1 and 89.8 ± 28.7 , respectively. On both occasions the distribution of flies matched the final distribution after 24 h. This would not have been the case if following were of major importance as the distribution should then show clumps of flies in particular collection tubes.

Wall-hugging (following the outer walls of the maze) and its converse, **centrifugal swing** affect maze performance in other invertebrates¹⁰. These factors may be relevant in other *Drosophila* maze studies^{8,11} but are less likely here, where the junctions have many small corners with both curved and flat surfaces to be negotiated (Fig. 1, detail). Moreover, observations of flies in transparent-topped mazes show that they can explore a junction for as long as 45 min before proceeding, rather than going straight through the maze, as a wall-hugging and centrifugal swing hypothesis would require.

Right-left bias. At the initial choice point, flies are being separated by their preference for turning left or right and it is simply those strains with a greater initial bias in one direction or another that are more likely to repeat the choice at the second choice-point. Turning seems to be probabilistic, however, and there is no evidence that some individual flies consistently turn left and others right. All the flies reaching the +5 tube during the five trials of each strain were stored on fresh food and rerun through the maze (-5 flies were similarly treated). If the bias explanation were correct, then the +5 and -5 flies would be those with a strong bias to turning left or right respectively at choice-points in the maze. Presumably this bias should be indicated on the rerun by increases in the initial probability of going left (PL) for the +5 flies, and right (PR) for the -5 flies, but in none of the 10 strains were the values of PL and PR significantly different from the original values in Table 1. Similarly, 27 generations of separate selection (from an F_2 population) of flies going to +5 or -5 has produced some increase in CL and CR, but not the change in PL and PR that a bias explanation would predict (D.A.H., unpublished). Also, if a right-left bias were important, the probabilities of repeating the same response at the third and final choice-point should be higher than the earlier probabilities. The opposite is the case, although possibly this third choice is affected by the flies being close to the end of the maze and being able to smell the food medium in the collection tubes (see Fig. 1) and so need not imply that learning has been lost by this stage of the maze.

Sequential alternation. When an organism is forced to turn one way in a maze and then given a choice, it will sometimes turn the opposite way, demonstrating what is termed sequential alternation⁴ or correcting behaviour¹². Although this may be considered a form of learning—the animal must retain some memory of the way it was forced to turn—and could be important in other mazes where passages are not blocked off and where *Drosophila* do repeat turns or sequences of turns⁸⁻¹¹, it cannot be the sole explanation here, for the same reasons that wall-hugging and centrifugal swing have been excluded.

Additional possibilities such as the olfactory cues postulated in other maze studies¹³ have been tested and excluded. The remaining explanation is that the flies display associative learning. With no apparent positive or negative reinforcement, they associate passage through the maze towards the light with a sequence of turns or, more accurately, with a particular orientation towards the light at each choice-point, since, as mentioned previously, flies may move about the junction for a considerable time before actually making the choice. Thus the behaviour here can be considered a form of the exploratory learning which is well-documented in the feeding and homing

of other arthropods¹⁴. Putnam⁹ has explained similar behaviour in the beetle *Aleochara bilineata* as evidence of learning—the beetles make the first choice in a Y maze at random, but the probability of repeating this choice increases on successive trials even without extrinsic reinforcement. He ruled out alternatives like right-left bias and odour cues discussed here, and concluded the beetles learn they can proceed through the maze by turning in this direction. As they never try turning the opposite way at a choice point, they do not find that this alternative response would be equally effective. Both there and in the present mazes, mere progress seems to constitute some differential reinforcement for repeating the same choice. Putnam also refers to work on rodent learning in mazes with reinforcement in both arms that can be explained in the same way.

Thus, genetic differences in learning have been demonstrated in *Drosophila*. The learning task is unusual but allows large numbers of flies to be scored, as it only requires the introduction of flies into the start tube and scoring 24 h later of the final distribution in the collection tubes. As there is no other interference by the experimenter, it should prove easier to replicate these results than has been the case with other *Drosophila* learning situations¹⁵. Like the aversive conditioning techniques¹⁻³ learning is being considered here at the population, rather than the individual level. But there has already been considerable success in the genetic analysis of taxes in mazes similar to these⁵, and the present technique may offer an effective screen for localising chromosomal factors determining the learning ability of *Drosophila*.

I thank E. Mintzis for assistance and E. Dempster, J. Grossfield and L. McCauley for comments on the manuscript.

Two photosystems controlling behavioural responses of *Halobacterium halobium*

Halobacterium halobium contains a retinal-protein complex, bacteriorhodopsin, which is the only protein of the so-called purple membrane forming distinct patches within the surface membrane^{1,2}. Bacteriorhodopsin acts as a photoreceptor molecule and is chemically similar to the visual pigment rhodopsin^{1,3}. On illumination bacteriorhodopsin undergoes a fast cyclic photoreaction with at least four intermediates occurring after microseconds and milliseconds⁴⁻⁶. Various experiments indicate that bacteriorhodopsin functions as a light-driven proton pump which builds up a proton gradient across the cell membrane and is used for ATP synthesis^{7,8}. Thus its primary function, different from that of rhodopsin in the eye, seems to be energy transformation⁷. Moreover, *H. halobium* shows light dependent motor responses, and so we supposed that bacteriorhodopsin also has a sensory function. To test this possibility we obtained action spectra for the light-induced behavioural responses from *H. halobium*. We

Fig. 1 *a*, Action spectrum of the inverse photophobic response (IPR) of *H. halobium* occurring after decrease of light intensity. Background illumination ($\lambda = 420\text{--}490\text{ nm}$) was given through the condenser of a phase contrast microscope. Stimulating light (half width $\leq 10\text{ nm}$) generated by a xenon source (XBO 150 W) or a mercury lamp (HBO 150 W) in connection with a high intensity grating monochromator, Bausch and Lomb, visible range, or a Zeiss monochromator type M4 QIII, respectively, was applied through a quartz objective connected with an incident light illuminator. Light intensity was measured by means of a light detector UDT 40 connected with pin 10 or pin 10 ultraviolet calibrated against a thermopile. Ordinate: sensitivity in log units given as the reciprocal of the change in light intensity which evokes the response after 1.9–2.0 s. Standard deviation of the means does not exceed the diameter of the points ($n = 4$). Room temperature. *b*, Absorption spectrum of the isolated purple membrane (bacteriorhodopsin) in H_2O after purification on a linear sucrose density gradient.

found two photosystems, one of which shows that bacteriorhodopsin is involved in the light-controlled motor response.

Experiments were performed with the mutant strain R_1 of *H. halobium*, lacking gas vacuoles. The bacteria were usually in the stationary growth phase, during which a maximum of purple membrane is present. These rod-shaped bacteria are about 4–10 μm long and 0.5–0.7 μm in diameter. Tufts of flagella on both poles, visible in electron micrographs of negatively stained bacteria, enable the cell to swim in both directions of its long axis. The mean swimming rate was 2.3 $\mu\text{m s}^{-1}$ (at 24 °C). Sudden changes in light intensity elicit a phobic response. After a latent period of about 1 s the bacterium stops moving for about 1 s and after axial rotation starts swimming in roughly the opposite direction. Similar responses can be evoked either by an increase of light intensity, called⁹ the direct photophobic response (DPR), or by a decrease of light intensity, the inverse photophobic response (IPR). In both cases the time elapsed between the beginning of stimulus and the first visible response depends on intensity, duration and wavelength of the stimulus.

Action spectra of the DPR and the IPR were obtained by measuring the stimulus intensity at the threshold. Single bacteria in a suspension were observed microscopically and the stimulus intensity at different wavelengths was varied until 19 out of 20 specimens examined showed the stop reaction within the time interval from 1.9 to 2.0 s after the onset of stimulus. Stimuli were always maintained until completion of the phobic response.

The action spectrum of the IPR (Fig. 1*a*) shows a single maximum of sensitivity at 565 nm which corresponds to the peak of absorbance of bacteriorhodopsin in the visible (Fig. 1*b*).

At wavelengths shorter than 460 nm no IPR could be elicited. We call this photosystem PS 565 and assume that its effective pigment is bacteriorhodopsin. This interpretation is supported by the fact that bacteria from young cultures which have not yet synthesised the purple membrane did not show the IPR. The absence of a 280-nm band in the action spectrum can be explained by (1) the probably insufficient intensity in the ultraviolet of the light source and (2) the limited energy transfer from the protein part to the excitable site of the pigment molecule, as found in frog rhodopsin¹⁰.

In the conditions described above a decrease of light intensity of 720 nW mm^{-2} , that is 2×10^{12} quanta $\text{mm}^{-2} \text{s}^{-1}$, at 565 nm was required to elicit the IPR. From the dependence of the threshold on the latent period the absolute threshold intensity was calculated to be 2×10^{11} quanta $\text{mm}^{-2} \text{s}^{-1}$, corresponding to an estimated 6×10^5 quanta per bacterium per s or 2 quanta per molecule bacteriorhodopsin per s. This relatively low sensitivity compared with that of animal photoreceptor cells indicates that amplification is absent or much less developed. Neither intensity nor wavelength of background illumination affected the height of the threshold. Thus adaptation defined

Fig. 2 *a*, Action spectrum of the direct photophobic response (DPR) of *H. halobium* occurring after increase of light intensity. Background illumination $\lambda > 645\text{ nm}$; half width of stimulating light 0.5–5.0 nm. Ordinate: Sensitivity as in Fig. 1*a*. Mean values of 3–11 measurements (\circ) or single values and means of two (\bullet). Vertical bars represent the standard deviation of the mean. Room temperature. *b*, Absorption spectra of a retinylidene protein obtained after treatment of the purple membrane with 10 mM CTAB (cetyltrimethyl-ammoniumbromide) at $\text{pH} \geq 8.5$ (—), of riboflavin in H_2O (---) and of methanol/ether extraction of pigments from *H. halobium* (mainly α -bacterioruberine) after separation of the purple membrane (....)

as change in sensitivity due to background illumination is absent in PS 565.

The action spectrum of the DPR (Fig. 2a) has two distinct maxima at 280 and 370 nm and smaller secondary peaks towards longer wavelengths. Beyond 530 nm no response could be evoked. With regard to the major peaks we believe a chromoprotein to be the effective pigment of this photosystem, which we call PS 370. The action spectrum resembles the absorption spectrum of a retinylidene protein which can be obtained by CTAB treatment of the purple membrane at alkaline pH (ref. 1) (Fig. 2b). The small peaks in the action spectrum beyond 400 nm may be due to the large amount of carotenoids, mainly α -bacterioruberine¹¹ (Fig. 2b) which could participate in the photoreception or act as a shielding pigment. If the latter is true, the photoreceptor pigment could be a flavoprotein (Fig. 2b), which we consider the more likely because of the marked decrease in sensitivity close to 500 nm. A flavoprotein has also been proposed as a photopigment for other bacteria¹².

To elicit the DPR within a latent period of 2 s a stimulus intensity of 80 ± 10 (s.d.) nW mm⁻², that is $(1.5 \pm 0.2) \times 10^{11}$ quanta mm⁻² s⁻¹ ($n = 7$) at 370 nm and of 3.5 ± 0.8 nW mm⁻², that is $(5.0 \pm 1.2) \times 10^9$ quanta mm⁻² s⁻¹ ($n = 11$) at 280 nm was required. The absolute threshold at 370 nm was calculated to be 1.5×10^{10} quanta mm⁻² s⁻¹. With blue background illumination ($\lambda = 420$ –490 nm) the threshold was 50 times that with red background illumination ($\lambda > 645$ nm) of equal intensity (4 mW mm⁻²). PS 370 developed about 10 h earlier than PS 565 and reached maximal sensitivity immediately whereas the latter was maximally sensitive after 40–50 h. When stimulus intensity and duration were varied the product of both (Bunsen–Roscoe rule) at threshold was constant in PS 370, but not in PS 565.

Our experiments demonstrate that *H. halobium* has two photosystems, as also suggested by H. Berg (personal communication). Both trigger flagellar responses and can be considered as sensory mechanisms. A sensory function implies that the stimulus controls a process which is provided with energy from other sources, that is that the important process is not transduction of energy but of information. Signal amplification, however, as in photoreceptor cells of animals seems not to be essential. Thus, besides the energy-converting function, bacteriorhodopsin acts as a signal transducer.

At present we have no clear idea how sensory transduction may function in *H. halobium*. In PS 565 the excitation could be triggered directly either by light-induced changes in the proton gradient or by an electrical potential across the cell membrane, which might be generated by the electrogenic proton pumping function of bacteriorhodopsin^{13–15}. Control of the motor response through a decrease of stored cellular energy, however, seems unlikely because, among other reasons, of the relatively short latent period even with green background illumination of high intensity, which should keep the cellular energy at a constantly high level. Nevertheless, the response could be triggered by one step of the energy-converting mechanism. If the photopigment of PS 370 is a flavin, a change in electron transport must be taken into account, as has been discussed for the light-induced tumbling effect in *Salmonella typhimurium*¹². By analogy with other cells exhibiting sensory properties, such as receptor cells and protozoa, it should be remembered that changes in the permeability of the cell membrane for certain ions could be mediated by the photosystems and that resulting passive ion fluxes lead to changes in flagellar activity.

The biological relevance of the sensory function is obvious for PS 565. The bacteria do not respond when entering an area of visible light but always reverse their direction if they cross to the dark. Thus they will be trapped in the light which can be used for ATP synthesis. By means of PS 370 the bacteria could avoid ultraviolet radiation which would damage the organisms, as has been shown with mutants lacking carotenoids¹⁶.

We thank Dr H. Falk for electron micrographs, Dr D.

Oesterhelt for a culture, and Dr H. Stieve for reading the manuscript. This work was supported by the Deutsche Forschungsgemeinschaft.

Correlation of electrical and mechanical responses in nervous control of cilia

ALTHOUGH cilia have many important functions in the majority of animal phyla, our knowledge about the mechanism by which their activity is controlled has been fragmentary¹. Extensive electrophysiological studies of the ciliated cell, with intracellular microelectrodes, have been made only with the relatively large protozoans, principally *Paramecium*, where the ciliary activity has been shown to be closely associated with the electrical properties of the cell membrane^{2,3}. Among the metazoans, some examples of nervous control of ciliary activity have been reported⁴, but, mainly because of technical difficulties, intracellular recording of the membrane potential from the ciliated cells has been made in only a few cases^{5,6}; in no case has nervous control of cilia been studied by recording simultaneously the electrical and the mechanical events. Such recording is essential to understanding the mechanism of nervous control at the cellular level.

Using the nerve–cilia preparation made from the gill of the bivalve mollusc, *Mytilus edulis*, we have been able to obtain simultaneous records of neurally evoked mechanical and electrical responses of the ciliated cell. The 'lateral' cilia in this preparation have been known to show an abrupt inhibition of motion, the ciliary arrest response⁷, in response to nerve stimulation, as well as an increased beat frequency which usually follows prolonged repetitive stimulation of the nerve⁸.

A nerve–cilia preparation, consisting of the visceral ganglion and a few gill filaments linked together by a branchial nerve, was dissected out as described previously⁷. From this a nerve-supplied single gill filament preparation was obtained by removing all gill filaments except one. The gill filament was then held, with one of its lateral surfaces facing downward, on the underside of a coverslip placed over a specially designed chamber. A glass capillary electrode with a vertically bent tip, filled with 1.5 M potassium citrate and having a resistance higher than 140 M Ω , was used to penetrate the lateral cell from below. Electrical stimuli were given to the nerve at a distance of 17–20 mm from the site of microelectrode penetration. The mechanical activity of cilia was monitored by projecting their microscopic image through a pinhole on to a photomultiplier tube. The output from the photomultiplier and the membrane potential of the lateral cell were simultaneously recorded on magnetic tape or photographed directly from the oscilloscope screen. The distance between the sites

of recording of the electrical and the mechanical events was 10–20 μm .

With successful penetration, a more or less steady resting membrane potential of about 60 mV (inside negative) was obtained; penetrations which gave potentials less than 30 mV were discarded as these were often followed by a slow depolarisation to zero level. There was no change in the membrane potential corresponding to the cyclic beating of cilia.

When the nerve was stimulated with a 2-ms pulse, there was a transient depolarisation of the lateral cell membrane which took place after a latency of about 120 ms, accompanied by a quick arrest response of the lateral cilia as shown in Fig. 1. The electrical response could be recorded only from the ciliated lateral cells and not from any adjacent regions of the epithelium. The electrical response lasted some 200 ms, of which the depolarising phase (time to peak) was about 30 ms. The amplitude of the response was not constant, but was usually less than 20 mV (mean of 26 measurements, 12.5 mV, 22–25 °C). No overshoot was recorded throughout the experiments. There was a marked facilitation of the electrical response when the nerve was stimulated at about 5 Hz, and also a summation evident at 20–40 Hz.

Repetitive stimulation elicited a prolonged arrest response of the lateral cilia, even when the individual electrical responses were separated (Fig. 2). The mechanical response usually outlasted the repeated electrical responses. On the other hand, the onset of the electrical response preceded that of the mechanical response by about 30 ms. The mechanical response was observed when the electrical response was above about 2 mV, although the threshold depolarisation, as well as the latency, of the mechanical response could not be determined accurately with the present monitoring method.

These results indicate that the transient depolarisation of the lateral cell induced by nervous activity is correlated with the quick arrest response of the cilia, and not with the frequency increase nor with the initiation of each beat. We have previously shown that the response can be induced by a high concentration of potassium⁹, and also by an 'outward' electric current passed across the ciliated membrane¹⁰. The present results are in full accord with these and support the view that the animal can control the cilia by depolarising the cell membrane⁹. They also support the work of Mackie *et al.*⁶ who recorded electrical activity associated with the ciliary arrest response in the ascidian *Corella*.

Fig. 1 Ciliary arrest response in the gill of *Mytilus*, elicited by stimulating the branchial nerve with 2-ms pulse given at the beginning of the record *a*. Photoelectrically recorded activity of lateral cilia. Prevailing oscillatory pattern represents normal beating activity, momentarily suppressed after stimulation *b*. Intracellular recording of the membrane potential. Note that the onset of electrical response (depolarisation) precedes the mechanical response. Resting membrane potential: –60 mV (21 °C). A reference line indicating –10 mV is superimposed on *a*.

Fig. 2 Response to repetitive stimulation of the branchial nerve at about 2 Hz. *a*, Ciliary activity; *b*, membrane potential. Note that the ciliary arrest response outlasts the electrical activity. Resting membrane potential: –67 mV (26 °C).

In *Paramecium*, calcium has been known to play an essential role in the coupling between membrane depolarisation and the 'reversal' response of cilia³. In *Mytilus*, too, the arrest response seems to depend on calcium since it disappears in calcium-free media¹¹ and also since, in the 'model' cilia made by treatment with Triton X-100, a similar response can be induced by adding calcium ions to the medium¹². The mechanism underlying the arrest response seems to be fundamentally similar to that underlying the ciliary reversal response in Protozoa, as has already been pointed out^{6,9,13}. The ciliary reversal response in certain metazoans is also correlated with the electrical activity of the membrane^{14,15}.

To conclude, the present results support the hypothesis that the ciliary arrest response, as well as the reversal response, is controlled by a mechanism comparable with that which regulates the muscular contraction through membrane excitation and the action of calcium ions^{3,13}.

Concentration of mercury by three species of fish from Japanese rivers

THE concentration of mercury in aquatic organisms is quite high relative to that in the surroundings but the exact mechanism by which this effect occurs is not known. Generally, higher mercury levels in the environment are reflected in the amount found in protoplasm. Mercury levels in rivers and lakes have increased markedly as a result of industrial discharges; thus, there is a proportionality between mercury concentrations in fishes and in waters, it is possible, using permissible mercury concentrations in fish tissue as a guide (Japan 0.4, US 0.5 p.p.m.), to

make recommendations for acceptable mercury levels in lakes and rivers. I have found no reports regarding this relationship.

Mercury contents of two rivers receiving waste discharged from mercury mines of an unpolluted river, and of three species of fish (crucian carp, *Carassius carassius langsdorffii*; dace, *Triblodonhakonensis*; zacco temmincku, (Temmincket Schlegel)) feeding mainly on organic matter in water, were determined. Rivers studied were the Hoono in Nara Prefecture, and the

increases in SO_2 concentrations in the presence of oxidants may result in a potential health hazard.

Subjects were eight 19–25-yr-old normal, non-smoking male university students with no history of significant chest illness or atopic illness. They were exposed to SO_2 and O_3 in a chamber that has been described before². Ozone was generated by electrical discharge in oxygen, and SO_2 (partially diluted with air) was added to the chamber from a cylinder. SO_2 and O_3 were added to the inlet of the chamber, and both gases were sampled about 2 feet from the nose of the subjects. Since O_3 will interfere with the analysis of SO_2 and *vice versa* we used scrubbers connected to the intake tubing of the analysers to remove the interfering gas.

SO_2 was removed from the intake, sample tube to the O_3 meter (Mast model 724-2) by a scrubber of glass fibre paper impregnated with chromium trioxide in 60–70% sulphuric acid. O_3 was removed from the sampling tube to the SO_2 meter (SI model 67) by a scrubber of crystals of ferrous sulphate heptahydrate.

As the exposure chamber was in a laboratory, in an air-conditioned building without externally opening windows, we assumed that the temperature and humidity varied little from day to day, and there was negligible particulate pollution. Since the atmospheric levels of SO_2 and O_3 were below 0.1 p.p.m. at the time of exposures, the contamination of the experimental atmosphere was unlikely.

All experiments followed the same protocol. Control pulmonary function was tested at time zero, and subjects then exercised on a bicycle ergometer at a work rate sufficient to double their ventilation for 15-min periods, alternating with 15-min rest periods for 2 h. They were tested again at 30-min intervals from the onset of exposure (0.5, 1.0, 1.5, 2.0 h) with a final test 30 min after the end of exposure.

Forced expiratory flow–volume curves were recorded by a Fleisch No. 3 pneumotachograph connected to a differential pressure transducer (HP model 270) and coupled to a carrier preamplifier (HP model 8805A). The resulting flow signal was displayed against volume on a storage oscilloscope equipped with dual trace amplifiers, volume being obtained by integration of flow signal.

This volume signal was recorded simultaneously on a four-channel FM tape recorder for later tracing of a spiogram. Four flow–volume curves were recorded on each occasion, and the definitive value was taken as the mean of the two largest values of the four. In addition to the dynamic lung function tests, six slow vital capacity curves were measured, three before and three after the exposure.

We have already described the effect of 0.37 p.p.m. of ozone

on human pulmonary function, finding a just significant decrease in maximal mid-expiratory flow rate (MMFR) at the end of 2 h (ref. 3). We now report that SO_2 , when present alone at a concentration of 0.37 p.p.m. had no significant effect on ventilatory function in 2 h. These results are shown in Fig. 1, which also shows the decline in this measurement of ventilatory function when both gases were present together. Clearly, at concentrations of this magnitude, the two gases together have a much greater effect than does either individually.

As in previous tests of human response to air pollutants, there was considerable individual variation. The largest decrease in maximal mid-expiratory flow rate was from an initial value of 7.93 l s^{-1} to 2.78 l s^{-1} at the end of 2 h, and the smallest reduction was from a control value of 8.74 l s^{-1} to 7.98 l s^{-1} after 2 h. For the group as a whole, the change after 30 min of exposure (from a mean of 6.49 with s.d. of ± 1.72 to a mean of 5.60 with s.d. of ± 1.63) was already significant at the 2% level. Other measurements of ventilatory function computed from either expiratory flow–volume curves or spiograms also decreased progressively during the same 2-h experiments.

The forced expiratory volume in 1 s ($\text{FEV}_{1.0}$) decreased to 78% of its initial value at the end of 2 h when both gases were present; the mid-expiratory flow rate, at 50% of vital capacity, decreased to 54% of its initial value in this atmosphere and the peak expiratory flow rate decreased to 79% of its initial value. The vital capacity, measured as a static, non-forced parameter of function, was 92% of its initial value at the end of 2 h exposure for the group as a whole. The decrease in the flow measurements was thus proportionately much greater than the decrease in static volume.

The enhancement of the toxicity of SO_2 and O_3 , present together, has been known for plants for some years⁴. As the simplest approximation, one can imagine the two gases interacting rapidly in the humidified air of the airways and on the large, wet air–tissue interface of the lung, painting the inner surface with sulphuric acid.

Are these experiments reliable indicators of what may be happening outside the laboratory? Lebowitz *et al.*⁵ have demonstrated a decline in ventilatory function in children and adolescents after outdoor exercise on days of relatively high pollution in Tucson, Arizona. Their air pollution data suggest that the interaction of oxidants and sulphur dioxide and sulphate produce the effect, since the levels of nitrogen dioxide and particles were not high enough to cause decline in function.

Are these experiments useful indicators of acceptable and unacceptable environments? At the very least, we can conclude that it is unwise to consider quantitatively acceptable levels for single pollutants when synergism among various pollutants may occur. Nevertheless, in our view, those environments with high enough levels of mixed pollutants to cause discomfort or even adverse changes in pulmonary function on moderate physical activity, should not be acceptable. Furthermore, we can safely assume that the long-term consequences of such repetitive insults may well result in serious lung damage.

Immunologically-mediated restraint of latent tumour metastases

DIFFERENT grafted sarcomas, all originally from chemically-induced autochthonous tumours, vary widely in their capacity to form metastases, as determined by the incidence of secondaries which appear in the lung and lymph nodes in the months following surgical removal of the 'primary' transplant from syngeneic rats¹. Tumours which do not form metastases readily in normal animals can be induced to do so by grafting into syngeneic rats depleted of T lymphocytes by procedures which do not compromise the bone marrow¹. We concluded that specific immune processes requiring the participation of T lymphocytes contributed to the control of metastatic spread—possibly by reducing the number of tumour cells released because there is an inverse relationship between the number of macrophages within the tumour and metastasis^{1,2}. In addition, circulating tumour cells may be destroyed immunologically and an immunologically-specific factor that acted against intravenously-injected sarcoma cells was demonstrated in the serum and lymph of tumour-bearing rats^{3,4}.

The experiments which we now report illustrate a further mechanism by which host immunity may control the development of distant metastases. Pure-line Hooded rats received transplants of the syngeneic 3,4-benz-pyrene-induced sarcoma HSBPA into the left leg, and 2 weeks later the tumours and their local draining lymph nodes were removed by amputation of the whole limb as described previously¹. Figure 1 shows that approximately 10% of the animals so treated died of distant metastases 55–100 d after removal of the tumour, the rest remaining tumour-free during the observation period of 18 months (that is, more than half of their normal lifespan). If the rats were exposed to either whole-body X irradiation, or to 7 d continuous draining of the thoracic duct lymph at different times after the removal of the primary transplant (the longest interval so far studied being 1 month), however, there was a highly significant increase in the incidence of distant metastases compared with the control group. In addition, it was noted that individual animals had more tumour lesions in both lymph nodes and lungs than control animals, and that their deaths due

to metastases frequently occurred earlier—especially in groups treated soon after surgery.

Although both whole-body irradiation and severe lymph depletion affect many different aspects of the animal's physiology, their main common feature is that of suppression of lymphocyte-mediated immunity, and it seems likely that this factor is responsible for their similar effects on the growth of metastases. Reconstitution experiments to determine whether the induction of metastases by these procedures can be reversed by giving syngeneic lymphocytes are in progress.

The fact that immunosuppressive treatments, even when given 1 month after surgical removal of a tumour, increase the incidence of metastases, excludes the possibility that in this case we are dealing with an effect on circulating tumour cells. We conclude that even sarcomas which normally are essentially non-metastatic shed cells which lodge and survive in the lung and lymph nodes, where they remain in a viable state without growing into macroscopically detectable lesions. Immunosuppression of the host permits such cells to develop into lethal tumours. This observation does not preclude some form of immunological control before these cells lodge themselves in the lung and lymph nodes, as the incidence of metastases reported here for postsurgically-immunosuppressed animals is not as high as that reported previously for the same tumour when immune suppression was applied during the period of tumour growth¹.

The existence of dormant cells which retain the potential to grow in rats from which the primary transplants have been surgically removed is paradoxical, as these same rats are capable of rejecting inocula of up to 10^7 cells given intramuscularly¹. Indeed, the claim that the tumour is highly immunogenic rests on this finding. We are now attempting to discover if these latent metastases persist as single cells, avascular clusters, or microfoci which are undergoing cyclical growth and regression. One fact seems clear—that at least half of the animals, seemingly cured surgically, carry dormant tumours that manifest only after treatments which are immunosuppressive. These experiments suggest a cautious approach to the use of chemotherapy for dealing with disseminated cancer cells which may be present after all clinically detectable tumour has been removed by surgery or radiotherapy, as such prophylactic systemic chemotherapy is often immunosuppressive. Prophylactic chemo-

Fig. 1 Effect of postsurgical immunosuppression on incidence of metastases after excision of HSBPA tumour. HSBPA tumours were grown intramuscularly in hind limbs of Hooded rats for 14 d, and removed by amputation of the whole limb. Immunosuppressive procedures were initiated 1, 7 or 30 d after tumour excision. These were: chronic thoracic duct lymph drainage (lymph was drained for 7 d during which time $1-3 \times 10^8$ lymphocytes were removed, and the cannulae were then tied off); and whole-body irradiation (rats were given

one sublethal dose of 500 rad X irradiation from a conventional Marconi machine at 220 kV, 15 mA and 54 cm FSD). *a*, No treatment (controls; $n = 80$); *b-d*, thoracic duct lymph drainage ($n = 20$ in each case); *b*, days 1–7; *c*, days 7–14; *d*, days 30–37; *e-g*, whole-body irradiation: *e*, day 1; *f*, day 7; *g*, day 30. Deaths: ●, with no evidence of metastases; ○, with lymph node metastases; ■, with lymph node and lung metastases; □, with lung metastases. I, irradiation carried out on days indicated by arrows

therapy is clearly of value when progressive microlesions are present, which if not eradicated would definitely develop into overt metastases; but it may be harmful when the disseminated tumour cells are dormant.

Stimulation of hepatocytes and lymphocytes *in vitro* by liver regeneration

We have reported the presence of serum factor triggering DNA synthesis in partially hepatectomised rats, using a parabiosis with direct aortic cross circulation¹. The finding was subsequently confirmed with experiments both *in vivo*² and *in vitro*³. We have also reported that partial hepatectomy stimulated function of lymphoid tissues and increased the number of antibody-forming cells in the spleen of rats immunised with sheep red blood cells⁴. It was then not certain how hepatectomy modifies the immune reaction, but now we present evidence that the humoral factor stimulates both hepatocytes and lymphocytes in culture.

Male Lewis rats (80-100 g) were subjected to 70% partial hepatectomy under ether anaesthesia in the morning⁵. Sham operation consisted of an abdominal incision and gentle palpation of the liver. All rats were anaesthetised again with ether 8 h after operation and were exsanguinated by cardiac puncture. Pooled blood was stored overnight at 4 °C, and then the serum was obtained by centrifugation. The serum was kept frozen at -20 °C until used.

Primary liver cell cultures were derived from livers of Lewis rat foetuses at 18-20 d gestation. Single cell suspensions were prepared after collagenase digestion of the tissue⁶. The viability of the cells was 85%, as measured by the Trypan blue exclusion test. The cells were grown in Falcon plastic dishes (35 mm) containing Eagle's MEM which was supplemented with non-essential amino acids, antibiotics, and 10% heat-inactivated foetal calf serum (Grand Island Biological). The initial cell inoculum was 5×10^5 per 2 ml per dish and maintained at 37 °C in a 10% CO₂-air incubator. The medium was changed 24 and 48 h after plating. At 4 d, the old medium was removed from the cultures and the dishes were washed with serum-free medium. Fresh medium (2 ml) containing the serum to be tested at a final concentration of 10%, was added to the culture along with ³H-thymidine (2.5 µCi ml⁻¹). After incubation at 37 °C for 24 h, the medium was removed and the dishes washed twice with Tris buffered saline (pH 7.4). A sample (2 ml) of a 0.05% trypsin solution in Ca²⁺- and Mg-free Tris buffer

were added to the dish and incubated at 37 °C for 30 min. The resulting cell suspension was used to determine the cell number and radioactivity of acid-precipitable material in a Packard scintillation counter. Identical experiments were performed with the foetal kidney cell culture.

To test the effect of partially hepatectomised serum on lymphocyte replication, lymphocyte suspensions were made from the cervical and mesenteric lymph nodes of Lewis rats. The culture medium used was the same for the foetal liver cell culture except that 10% heat inactivated rat serum (pooled from BN strain) was used instead of the foetal calf serum. To show that the 10% foetal calf serum was mitogenic to the rat lymphocyte in our hands, it was substituted for the rat serum which gave a low control value. The initial suspension contained 1×10^6 cells per 2 ml in sterile Falcon plastic culture tubes. The cells were cultured undisturbed for 4 d and supplemented with fresh medium containing the serum in question as mentioned above. At the end of the culture (day 5) smears of cell suspensions were made and stained with Wright-Giemsa. The percentage of mitoses was determined in counts of 1,000 cells. DNA synthesis was also estimated in all experiments by the incorporation of ³H-thymidine.

Results of the ³H-thymidine incorporation into liver cells and lymphocytes are shown in Table 1. A marked increase of DNA synthesis was seen in the liver cells cultured with partially hepatectomised (PH) serum (Table 1, left column). Serum taken from either sham-operated syngeneic (Lewis) or allogeneic (BN) rats was also shown to be mitogenic to Lewis foetal liver cells, compared with the cells cultured without the rat serum. The results strongly favour the hypothesis that partial hepatectomy increased mitogenic serum factor³ but does not decrease inhibitor. No mitogenic effect of the PH serum was observed on the kidney cell culture (data not shown).

Surprisingly the PH serum was also stimulatory to lymphocytes (Table 1, right column). This effect is highly significant compared with either normal rat serum ($P < 0.001$) or sham-operated rat serum ($P < 0.001$). All three sera (NR, PH, and sham) showed significantly high uptake when compared with the culture without the serum. The stimulatory effect of the hepatectomised serum on lymphocyte replication was first seen after the cells were cultured for 8 h or more.

The number of cells in mitosis is shown in Table 2. The serum from partially hepatectomised rats stimulated mitosis of both liver cells and lymphocytes in culture significantly more ($P < 0.001$) than the sera from either normal or sham-operated rats.

Evidence suggesting the presence of regeneration factor in the serum of partially hepatectomised rats was first provided by Bucher *et al.*⁶ in experiments with simple parabiotic rats connected only with skin and muscles. It was firmly confirmed by a cross circulation of aortae of parabiotic rats; a significant increase in DNA synthesis in the normal liver of a parabiotic partner after a 70% hepatectomy of the other^{1,2}. Stimulating effect of the regeneration serum on the growth of fibroblasts⁷, cultured rat hepatocytes⁸ and foetal liver cells³ has since been reported.

Table 1 Stimulation of DNA synthesis as measured by incorporation of ³H-thymidine into hepatocytes and lymphocytes *in vitro* in the presence of serum from partially hepatectomised rats

Experiment	Foetal liver cells (c.p.m. per 0.5×10^6 cells per 24 h)				Lymphocytes (c.p.m. per 10^6 cells per 24 h)			
	NR serum	PH serum	Sham serum	No serum	NR serum	PH serum	Sham serum	No serum
1	6,350	13,100	5,190	2,380	2,000	5,130	1,750	1,060
2	9,100	17,500	6,500	3,590	2,150	4,200	2,010	870
3	5,300	11,000	5,900	4,070	1,550	3,950	1,310	690
4	6,100	9,500	4,850	3,410	1,900	4,100	1,550	930
5	5,050	12,600	3,760	1,820	1,610	3,500	1,600	770

Liver cells (left column) were cultured in 35-mm plastic dishes in 2 ml of Eagle's medium supplemented with 10% heat-inactivated foetal calf serum. On day 4, the old medium was pipetted and the cultures incubated for 24 h with 2 ml of medium containing either 10% normal rat (NR), partially hepatectomised (PH), sham-operated rat sera or no serum along with ³H-thymidine (2.5 µCi ml⁻¹). Lymph node lymphocytes (right column) were cultured in 5-ml plastic tubes in 2 ml of the medium with 10% heat-inactivated pooled homologous serum. Addition of the serum to be tested and assay for DNA synthesis were the same. Each experiment was done on 3 rats. Average of 3 dishes is shown for each experiment.

Table 2 The mitotic rate of hepatocytes and lymphocytes cultured with partially hepatectomised rat serum for 24 h.

Serum source	Mitosis (% mean \pm s.d.)	
	Foetal liver cells	Lymphocytes
Normal rats	4.83 \pm 2.01	0.28 \pm 0.16
Partially hepatectomised rats	9.05 \pm 2.64	0.87 \pm 0.20
Sham-operated rats	4.29 \pm 1.87	0.31 \pm 0.15
None	3.56 \pm 1.08	0.12 \pm 0.08

Culture conditions for both liver cells and lymphocytes are the same as shown in Table 1. At the end of the culture (on the day 5) smears of the cell suspensions were made and stained with Wright-Giemsa. The percentage of the mitosis was determined per 1,000 cells. The data represent means with standard deviations from total 15 cultures for each serum tested.

Partial hepatectomy leads to increased DNA synthesis not only in the regenerating liver cells but also in lymphoid tissues as measured by ^3H -thymidine uptake⁹. We have shown that partial hepatectomy affects the recruitment of thymus cells on the one hand, but on the other, it increases the number of antibody-forming cells by shortening their doubling time^{4,10}. It was then suspected that the regeneration serum might be mitogenic to both the hepatocyte and lymphocyte. For a technical reason in the present experiment, both types of cells, foetal liver cells and adult lymph node cells were treated slightly differently in that the former were cultured after collagenase digestion of the tissue and in a 10% foetal calf serum medium, whereas the latter were cultured in a 10% rat serum medium without the enzymatic digestion. While it might be argued that the enzyme and different serum sources might have triggered the membrane receptors of both cell types differently, these culture conditions would not be a decisive factor, since only the PH serum could stimulate the DNA synthesis of both cells when added at the end of the fourth day and cultured more than 8 h.

The breakdown of the peripheral lymphocytes took place 7-8 h after partial hepatectomy and the peak of RNA synthesis in the liver appeared at the same time. It is therefore possible that the breakdown product of the lymphocyte liberates other active agents independent of hepatotrophic factor, which stimulate increased precursor cell proliferation of the lymphocyte. Although the fact that the PH serum did not stimulate the cultured kidney cells suggests a hepatolymphatic interrelationship, it remains to be seen whether the serum factor(s) appearing after partial hepatectomy is multipotential, one factor triggering the hepatocyte replication and the other stimulating the lymphocyte, or unipotent, a factor regulating both cell types.

Separation of subfragment-1 isoenzymes from rabbit skeletal muscle myosin

RABBIT skeletal muscle myosin is composed of two heavy chains and four light chains¹. Two classes of light chains can be distinguished both chemically and functionally. Within the class of essential light chains (those which cannot be removed without loss of ATPase activity), two chemically related but phenotypically distinct proteins have been identified², both of which are present in single fibres of fast-twitch muscles³. The existence of both phenotypes within a single psoas muscle cell indicates that either there is a single population of myosin molecules with a different alkali light chain on each subfragment-1 head, or there are at least two populations of myosin present. Densitometric and radiochemical methods have shown that there is an unequal distribution of these two light chains; this supports the hypothesis that myosin isoenzymes occur in histochemically homogeneous muscles³⁻⁵ which cannot be attributed to the presence of contaminating slow-twitch fibres. The presence of different heavy chains also is indicated by the observation of amino acid substitutions in certain peptide sequences^{6,7}. Thus fast-twitch muscles contain myosin showing heterogeneity of both light and heavy chains, suggesting isoenzyme populations, but so far these have not been separated, nor have the proteolytic subfragments derived from them.

The smallest active fragment obtainable from myosin is the globular head called subfragment-1 (S-1), which is usually produced by brief papain digestion⁸. This subfragment has been used extensively for kinetic analysis of the ATPase activity⁹. Unfortunately it is even more heterogeneous than its parent myosin. Partial loss of the non-essential DTNB light chain is commonly observed on exposure of myosin to papain⁸, and the

Fig. 1 Polyacrylamide gel electrophoresis on 10% gels run in 0.1 M Tris-bicene and 0.1% SDS and stained as described previously³. a, Chymotryptic HMM; b, chymotryptic S-1; c, fraction S-1(A1) pooled from the DEAE-cellulose column; d, fraction S-1(A2) from the column; e, S-1(A1) from a single peak tube showing one heavy chain and the alkali 1 light chain.

Fig. 2 Chromatography on DEAE-cellulose (Whatman DE-52) was carried out at 4 °C using a 48 × 2.5-cm column in 50 mM imidazole-HCl buffer at pH 7.0. This S-1 was eluted with a linear gradient to 0.12 M NaCl and the absorbance was measured at 280 nm.

heavy chains show the presence of nicks when subjected to polyacrylamide gel electrophoresis in the presence of sodium dodecyl sulphate (SDS)^{8,10}.

To characterise the different isoenzymes of myosin it is essential to separate these S-1 fragments, and further to obtain species which do not contain adventitious proteolytic cleavage of the heavy chains. This has not proved possible using papain, but following some observations of Yagi and Otani¹¹, we have developed methods to produce selective cleavage of the myosin head, and have also been able to eliminate the DTNB light chains from the resultant S-1. Two populations of S-1 molecules are obtained; one contains the alkali 1 light chain [S-1(A1)] and the other, alkali 2 [S-1(A2)], and both give single heavy chain bands on polyacrylamide gels. The two populations have been separated by chromatography, modifying the procedure described previously⁸.

Rabbit myosin was prepared as described⁸, and digestion for 10 min at 25 °C in 0.6 M NaCl, 10 mM sodium phosphate, pH 7.0, at 10–20 mg ml⁻¹ using α-chymotrypsin at 0.05 mg ml⁻¹ produced heavy meromyosin (HMM), which was isolated in the supernatant after dialysis to an ionic strength less than 0.05. (Digestion was terminated by addition of 100 mM phenyl methane sulphonyl fluoride in ethyl alcohol to a concentration of 10⁻⁴ M.) Gel electrophoresis of this HMM is shown in Fig. 1; it contained a single heavy chain and three light chain bands. If the digestion was carried out on myosin filaments produced by dialysis to 0.12 M NaCl, 20 mM sodium phosphate, pH 7.0, and containing 1 mM EDTA, HMM was no longer produced; instead the product was S-1, which on gels showed a single heavy chain band and only two light chains (Fig. 1). Thus under these conditions the susceptibility of myosin to chymotrypsin is altered, and the S-1 obtained is both more homogeneous and less degraded than that produced by papain digestion.

With the DTNB light chain absent, we have been able to fractionate the two components in this S-1 preparation (Fig. 2). Gel electrophoresis of the products is shown in Fig. 1. Although the second fraction frequently contains some contaminating S-1(A1), the first fraction is remarkably clean, yielding a single heavy chain and one light chain which comigrates with alkali 1 light chain marker. The molecular weights obtained by low speed sedimentation equilibrium for these two components were in the range 116,000–126,000, similar to values obtained for papain S-1 (ref. 8).

ATPase activity was measured to investigate kinetic differences between the two S-1 fractions. The calcium ATPase, measured with a pH-stat, in 30 mM KCl, 10 mM CaCl₂ and 1 mM ATP at pH 8.0, showed no significant differences. For example, in one preparation the turnover number of S-1(A1) was 8.1 s⁻¹ and that of S-1(A2), 8.2 s⁻¹ (both based on a molecular weight of 115,000). In an earlier preparation which was not fractionated, the activity of 7.7 s⁻¹ was identical to that obtained for a parallel preparation of papain S-1.

The magnesium-dependent ATPase activity, measured by a linked assay system¹², again showed no significant differences between these fractions. The steady state rate was always in the range 0.04–0.05 s⁻¹, similar to published values for papain S-1 (ref. 12). When ATPase measurements were made in the presence of actin, striking differences were observed. In three different preparations we found that the V_{max} for S-1(A1) was about half that obtained for S-1(A2). One such experiment is shown in Fig. 3. The regression line extrapolates to give $V_{max} = 28$ s⁻¹ for S-1(A1), and 54 s⁻¹ for S-1(A2), while K_{app} , determined from the intercept on the abscissa is 10 μM actin for S-1(A1) and 50 μM actin for S-1(A2). By comparison, the V_{max} obtained for papain S-1 under these conditions was 40 s⁻¹.

Fig. 3 Lineweaver-Burk plot of actin-activated ATPase activity for S-1(A1) (○) and S-1(A2) (●). The assay mixture contained 6 mM KCl, 1.5 mM MgCl₂ and 1.0 mM ATP, and activities were determined in a pH-stat at pH 8.0, 25 °C. The error bars show standard deviations, with at least five determinations at each actin concentration.

We show here that isoenzymes of S-1 obtained by chymotryptic digestion of filamentous myosin, can be separated to give homogeneous S-1 fractions. Steady state ATPase activity measurements showed no significant differences in the absence of actin, while in its presence there was a twofold difference in the V_{max} obtained from Lineweaver-Burk plots. This kinetic variation may reflect a true distinction in the mode of interaction of these different myosin heads with actin, which might be dependent on the presence of different alkali light chains, but it could have arisen as a result of the proteolysis procedures or during purification. Experiments are in progress to explore this. Nevertheless, the results suggest that the structural heterogeneity determines kinetic differences between these S-1 species. It is now important to establish whether the heavy meromyosins

produced by chymotryptic cleavage can be separated, since this would provide unequivocal evidence for the existence of myosin isoenzymes.

The importance of these studies is that using chymotrypsin, homogeneous S-1 preparations can be obtained for the first time. Furthermore, since the specificity of this enzyme is for aromatic residues, which are frequently buried and inaccessible to solvent, this enzyme provides a particularly sensitive probe for the susceptible regions of the myosin molecule: digestion can be modified not only by the aggregation state of myosin but also by its ionic environment, since in the presence of divalent cations (magnesium or calcium), HMM is produced even at low ionic strength (our unpublished observations).

We thank Dr H. E. Huxley for helpful discussions and Mr R. Hall for technical assistance.

Induction of chromosome changes in Chinese hamster cells by exposure to asbestos fibres

THE occurrence of pleural and peritoneal mesotheliomata is linked with the inhalation of asbestos fibres^{1,2}. Experimentally, mesotheliomata have been induced by the intrapleural inoculation of asbestos fibres into rats³. These findings suggest that

the incorporation of the fibres disturbs processes at the cellular level. The possibility that they induce chromosome abnormalities was indicated by V. Timbrell (personal communication) and we have investigated it further using cultured Chinese hamster cells.

The cells were derived by cloning from a parental line CHO-K1 (American Type Culture Collection), a line which has previously been used in evaluating induced chromosome changes⁴. They were seeded at equal densities in 10 culture vessels containing Iwakata and Grace's modification of McCoy's 5a culture medium⁵ (foetal bovine serum level 10%). Pairs of flasks, with the exception of two unexposed control cultures, contained one of the following dusts at a concentration of 0.01 mg ml⁻¹, SFA chrysotile asbestos; UICC crocidolite asbestos; glassfibre and glass powder. These dusts have been described elsewhere⁶. The flasks were agitated to mix the cells and dusts thoroughly and after 48 h the cells from one member of each pair were collected, metaphase spreads being obtained by the standard procedure. Measurements of plating efficiency and viability (by the Trypan blue method) were made for each culture at the time of collection. Five days after seeding, the remaining cultures were processed in the same way. The slides were stained by the trypsin/Leishman banding method of Seabright⁶ and 100 suitable metaphases from each culture were studied.

The experiment was then repeated with the notable difference that the cells were treated after culture by a method of *in situ* fixation (to be published elsewhere) which avoided both mechanical handling (that is, centrifugation) and the use of proteolytic enzymes for cell detachment.

The results are summarised in Table 1 and show that karyotypic alterations were largely restricted to the cells exposed to asbestos. Prolonging the exposure period from 48 h to 5 d seems to have had little effect on the incidence of abnormalities, with the possible exception of the 5-d exposed SFA chrysotile group in which there was an increased trend toward cells with fragments. In this context, it is noteworthy that additional experiments in which asbestos fibres were preincubated in culture medium for a short period before coming into contact with cells revealed a reduced incidence of karyotypic abnormality, particularly in the case of the group exposed to UICC crocidolite.

This could indicate that components of the culture medium

Table 1 Effects of different treatments on chromosomes

	48 h exposure

Cells with fragments	34 (31)	14 (10)	0 (0)	0 (0)	0 (0)
Cells with other chromosomal changes	25 (19)	23 (30)	1 (0)	0 (0)	0 (1)
% Abnormal cells	79 (73)	53 (61)	8 (4)	5 (4)	2 (6)
(100 cells scored from each culture)					

The numbers in parentheses refer to results obtained by *in situ* fixation. The categories scored were not mutually exclusive. All the populations showed plating efficiencies > 89% and viabilities > 85% at the times of collection.

(for example, serum protein) interact with asbestos to produce alterations in the effective dose and exposure period within the experiments, such that after a fixed short period fibres were rendered ineffectual with regard to the production of genetic damage. This type of consideration may help to explain the similarity between the 48-h and 5-d exposure data.

The polyploid cells identified were largely cells with twice the modal number of chromosomes in the 48-h exposed groups and more than twice the modal number in the cultures receiving 5-d exposures. The cells classified with fragments (Table 1 and Fig. 2) included many changes at both the chromatid and chromosomal levels; chromatid breaks and paired isodiametric fragments (double minutes) as shown in Fig. 2b. In addition, chromosome type breaks and rearrangements were identified in some cells from the asbestos-treated cultures (Table 1 and Fig. 1), but not from the glass-treated or unexposed controls. The possibility that these may represent the selection of pre-existing clones is being examined in further experiments although this is not supported by ancillary evidence.

The inclusion of fibreglass and glass powder in the experiment as presumptively inert control dusts was prompted by the finding that, in contrast to asbestos fibres, neither gives rise to mesotheliomata when inoculated intrapleurally into rats³. It is noteworthy that polyploids were for the most part the only exceptional cells identified in the cultures exposed to these two dusts and that their incidence was no greater than in the unexposed controls. In the absence of other changes in the glass-exposed cultures it seems unlikely that the chromosomal abnormalities seen in the cells exposed to asbestos arose as a result of the mechanical handling (centrifugation) that followed cell culture. This is further confirmed by the results obtained

Fig. 1 a, Karyotype of unexposed cell. b, karyotype of cell exposed for 5 d to UICC crocidolite asbestos. Arrows indicate chromosomes that have undergone pericentric inversion. Chromosome 16 has broken in the region of its centromere and marker chromosome 20 is absent.

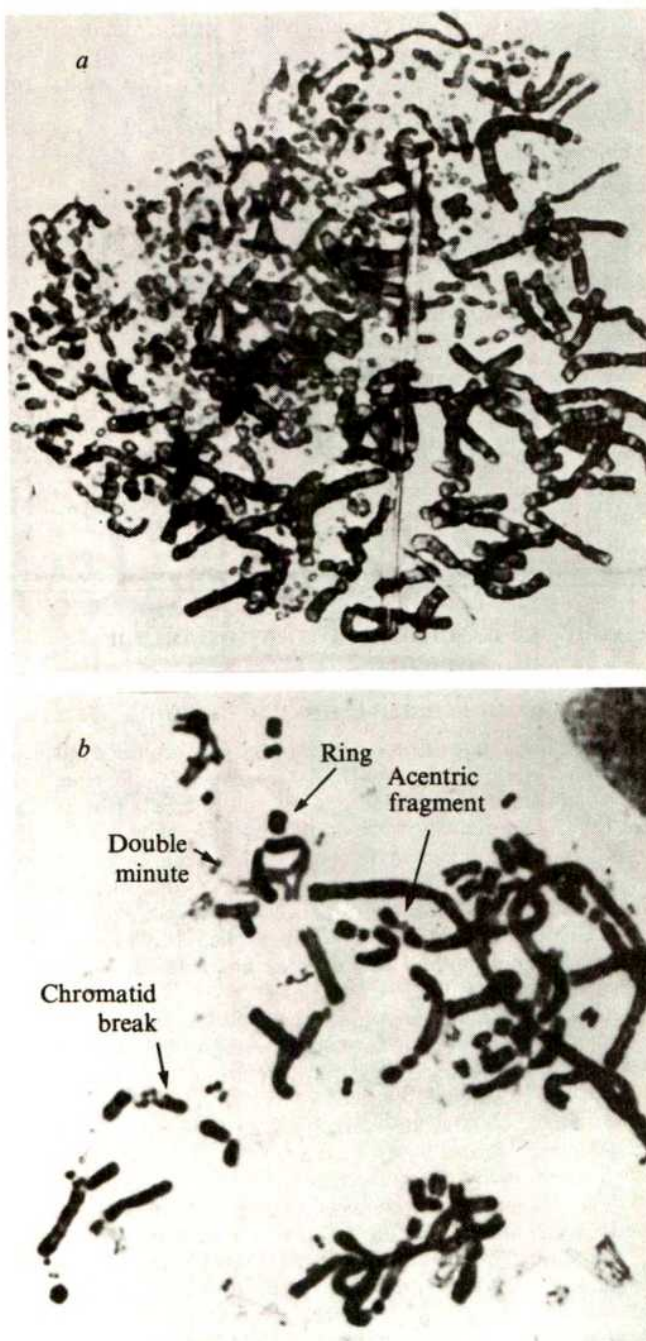

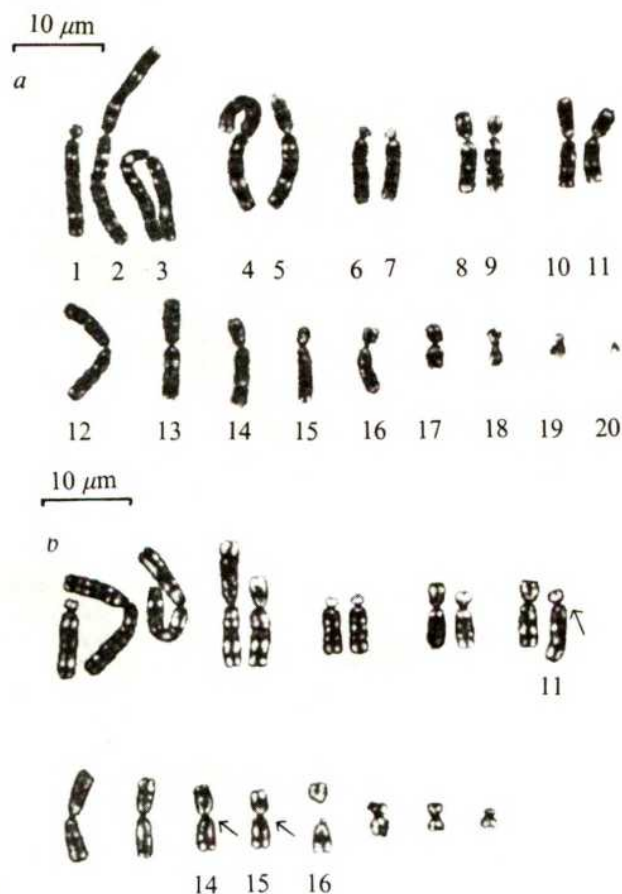

Fig. 2 a, Cell derived from a culture that had been exposed to UICC crocidolite asbestos for 5 d, showing multiple fragmentation in a situation of high ploidy. A fibre is seen at the centre of the field. b, Chromatid breaks and multiple aberrations in a cell derived from a culture exposed to UICC crocidolite asbestos for 5 d.

using an *in situ* fixation method (Table 1) which correlate closely with those obtained using standard procedures, although the method avoids both centrifugation and the use of proteolytic enzymes for cell detachment.

We conclude that multiple abnormalities at both the chromatid and chromosomal levels were produced in Chinese hamster cells as a result of the inclusion of asbestos fibre in their culture regime. Furthermore, these results, which were specifically produced by asbestos rather than the presumptively inert glass dusts, seemed to be largely unaffected by prolonging the exposure period. This preliminary detection of a mammalian cell response to asbestos *in vitro* forms the first stage of the development of an *in vitro* screening test for asbestos and other carcinogenic materials. In this it is envisaged that primary cells

will be cloned for specific chromosomal abnormalities and then introduced into laboratory animals to ascertain whether or not they induce tumours *in vivo*.

Cyclic AMP-mediated transformation of rat cells transformed by temperature-sensitive mouse sarcoma virus

SEVERAL lines of evidence suggest that adenosine 3',5'-cyclic monophosphate (cyclic AMP) is involved in the regulation of growth and other properties of cultured cells (for review, see ref. 1). Specifically, various reports have shown a correlation between the abnormal growth and morphological properties of virus-transformed cells and low levels of cyclic AMP^{2,3}. Treatment of these transformed cells with cyclic AMP, cyclic AMP analogues, or agents that raise cyclic AMP levels restores growth and morphological properties characteristic of normal cells⁴⁻⁷. The use of cells transformed by temperature-sensitive (ts) mutants of Rous sarcoma virus (RSV) or mouse sarcoma virus (MSV)^{8,9} as well as ts host cell mutants^{10,11} strengthened the evidence relating viral transformation and cyclic AMP levels. Other evidence obtained in similar virally transformed cell systems, however, has failed to confirm the inverse relationship between cyclic AMP levels and cell growth rate and transformation by RNA and DNA tumour viruses¹²⁻¹⁵. We now report that the exogenous addition of cyclic AMP mediates the morphological transformation of rat cells transformed by a ts mutant of MSV at the non-permissive temperature. Correspondingly, expression of the transformed phenotype by cells grown at the permissive temperature is associated with increased levels of endogenous cyclic AMP.

The cell lines used have been described before^{16,17} and included: (1) normal rat kidney (NRK) cells, (2) NRK cells transformed and productively infected with the Moloney sarcoma-leukaemia virus (NRK(MSV-MLV)), and (3) NRK cells transformed by a cold-sensitive mutant of MSV (NRK(MSV-1b)). The NRK(MSV-1b) cells express the transformed phenotype at the permissive temperature (39 °C) but appear phenotypically normal at the non-permissive temperature (33 °C). Cell lines other than NRK(MSV-1b) were routinely grown at 36 °C.

Preliminary experiments to investigate the effect of cyclic AMP on the morphological phenotype of uninfected and MSV-transformed NRK cells, demonstrated that 0.4 mM 8-bromo-cyclic AMP (8-Br-cyclic AMP) or 0.4 mM N⁶,O^{2'}-dibutyryl cyclic AMP (db-cyclic AMP) in combination with 1.0 mM theophylline were most effective in inducing the morphological changes presented in Fig. 1. The morphology of NRK(MSV-1b) grown at the non-permissive temperature (Fig. 1a) was changed perceptively after exposure to 8-Br-cyclic AMP or db-cyclic AMP (Fig. 1b). The effect was to change the morphological phenotype of NRK(MSV-1b) cells

Fig. 1 Effect of cyclic AMP on the morphology of NRK(MSV-1b) cells. NRK(MSV-1b) cells were seeded at 1×10^6 per 60-mm Petri dish and incubated at either 33 or 39 °C for 3–4 d in Eagle's minimal essential medium (MEM) supplemented with 10% foetal calf serum (v/v). They were then exposed to 0.4 mM db-cyclic AMP plus 1.0 mM theophylline or 0.4 mM 8-Br-cyclic AMP without replacing the growth medium. Twenty-four hours later photomicrographs were made with a phase-contrast microscope and were magnified $\times 190$. Solutions of cyclic AMP, cyclic AMP analogues, other cyclic nucleotides, adenosine compounds and theophylline in growth medium were prepared and Millipore-filtered (0.45 μ m) immediately before use. *a*, NRK(MSV-1b) cells grown at the non-permissive temperature, 33 °C, and mock-treated with growth medium; *b*, NRK(MSV-1b) cells grown at 33 °C and exposed to 0.4 mM db-cyclic AMP plus 1.0 mM theophylline for 24 h; *c*, cells treated as in *b*, reversed at 24 h by replacing the medium with growth medium, and photographed 2 h later; *d*, NRK(MSV-1b) cells grown at the permissive temperature, 39 °C, and either mock-treated with growth medium, or exposed to 0.4 mM db-cyclic AMP plus 1.0 mM theophylline for 24 h. Identical results were obtained using 8-Br-cyclic AMP in place of db-cyclic AMP and theophylline.

which at the non-permissive temperature, 33 °C, appear flattened and poorly refractile to a highly refractile, rounded, circular morphology, characteristic of NRK(MSV-1b) cells grown at the temperature (39 °C) permissive for expression of transformation (Fig. 1d). The morphological change was obvious within 10 min after exposure to 8-Br-cyclic AMP and achieved maximum expression by 1 h. Using db-cyclic AMP plus theophylline, morphological changes were obvious within 3 h and achieved maximum expression by 24 h. In both cases, exposure of NRK(MSV-1b) cells at 33 °C to the cyclic AMP analogues resulted in morphological alterations of 100% of the cells, and the cells remained morphologically altered as long as additive was present (up to 72 h). Removal of the cyclic AMP analogues, however, resulted in a rapid reversal (within 1 h) from the transformed to the normal phenotype (Fig. 1c). Furthermore, the morphological changes induced

by cyclic AMP were apparently independent of the growth state of the NRK(MSV-1b) cells, since identical morphological responses were observed in sparse and confluent cultures. The addition of cyclic AMP analogues to NRK (MSV-1b) cells grown at the permissive temperature (39 °C) did not alter the existing transformed phenotype characterised by rounded cells that grew in clumps or clusters. The exogenous addition of cyclic AMP analogues to uninfected NRK cells and transformed NRK(MSV-MLV) cells provoked no morphological changes in these cells whether cultured at 33, 36 or 39 °C, indicating that the cyclic AMP-mediated morphological changes were specific for NRK cells transformed by the cold-sensitive MSV mutant.

The specificity of cyclic AMP or analogues of cyclic AMP in inducing morphological transformation of NRK(MSV-1b) cells grown at the non-permissive temperature was investigated. The induced morphological changes were specific for cyclic AMP and cyclic AMP analogues and potentiated by theophylline. Cyclic GMP alone had no effect on the morphology of NRK(MSV-1b) cells and was not antagonistic to the effects of the cyclic AMP analogues. Molecules related to cyclic AMP, such as 5'-adenosine monophosphate (5'-AMP), 2',3'-AMP, adenosine, and adenine had no effect on change of cell shape. Similarly, other cyclic nucleotides such as cytidine 3',5'-cyclic monophosphate (cyclic AMP), thymidine 3',5'-cyclic monophosphate (cyclic TMP), uridine 3',5'-cyclic monophosphate (cyclic UMP), as well as theophylline and butyrate had no effect on the morphological phenotype of the cells.

One prediction of the cyclic AMP-mediated morphological transformation event would propose that intracellular cyclic AMP levels should be lower in the phenotypically normal cold-sensitive transformants grown at the non-permissive temperature, whereas higher levels of cyclic AMP might be expected in the same cells grown at the permissive temperature where the transformed phenotype is expressed. To test this prediction, intracellular cyclic AMP content was measured by a standard radioimmunoassay (Collaborative Research) as previously described¹⁸. NRK(MSV-1b) cells grown under permissive conditions contained levels of cyclic AMP approximately three times higher than the same cells grown under non-permissive conditions (Table 1). Levels of cyclic AMP remained 50–80% higher in cells grown at the permissive relative to the non-permissive temperature during the course of the experiment. Reciprocal temperature shifts of NRK (MSV-1b) cells grown at 39 °C or 33 °C resulted in marked changes in cyclic AMP levels (Table 1). Cyclic AMP levels increased approximately threefold within 5 h after a shift from non-permissive to permissive temperature and reached a level 24 h later similar to that of cells grown at 39 °C. In shift-down experiments, cyclic AMP levels fell more slowly with time, resulting in a 50% decrease within 24 h after shifting from the permissive to non-permissive temperature. The slower drop in cyclic AMP levels contingent with shifting from 39 to 33 °C may reflect the time involved in turnover of the residual cyclic AMP pool. Alternatively, the rate at which cyclic AMP levels decrease or increase after temperature shift may be controlled by temperature-dependent adenylate cyclase activity.

During these experiments, uninfected NRK and transformed NRK(MSV-MLV) cell lines were included at random in the experimental design and their cyclic AMP levels are presented in Table 1. No significant difference in cyclic AMP levels was found for NRK and NRK(MSV-MLV) cell lines under the conditions described.

Our observations of higher levels of cyclic AMP in NRK (MSV-1b) cells grown at the temperature permissive for expression of the transformed phenotype relative to the same cells grown under conditions non-permissive for maintenance of transformation parallels the morphological changes that occur after addition of cyclic AMP or cyclic AMP analogues to these cells. Recently, we have examined fucosylglycolipid metabolism as a biochemical marker of transformation²⁰.

Table 1 Cyclic AMP levels in NRK cells transformed by temperature-sensitive MSV

Expt	Time	pmol cyclicAMP per mg protein				NRK NRK (MSV-MLV)	
		NRK(MSV-1b)					
		33 °C	33→39 °C	39 °C	39→33 °C		
1	0 h	28*	28	90	90		
	5 h	41	111	63	80		
	24 h	39	69	69	59		
2	5 d					61	51

In experiment 1 NRK(MSV-1b) cells were seeded at 1.5×10^5 cells per Petri dish and incubated at 33 or 39 °C. Forty-eight hours later, half of the dishes at 39 °C were shifted to 33 °C, and vice versa. At the time of temperature shift (0 time), 5 h and 24 h later cyclic AMP content was determined. Medium was aspirated from the cultures, the cells were washed once with cold Gibco Solution A, and the cells were frozen by placing the Petri dishes on dry ice. The cultures were then overlaid with 1.0 ml of cold 6% trichloroacetic acid, and the cells were scraped off the dishes with a rubber policeman. The suspension was centrifuged at 10,000g for 15 min at 4 °C. The precipitate was assayed for protein by the Lowry method¹⁹, and the supernatant was assayed for cyclic AMP. The supernatant was extracted three times with 5 ml of water-saturated petroleum ether. The aqueous phase was heated to 70–80 °C for 2 min and then frozen at –70 °C. In some cases the aqueous phase after extraction was lyophilised and the residue was dissolved in 0.25 M phosphate buffer, pH 7.0. Cyclic AMP was assayed using a standard radioimmunoassay (Collaborative Research) as previously described¹⁸. Recovery of cyclic AMP during extraction was above 95%. In experiment 2 NRK and NRK(MSV-MLV) cells were seeded at 1.5×10^5 cells per Petri dish, incubated at 36 °C, and assayed for intracellular cyclic AMP 5 d later, as described above. The values represent the mean of three independent experiments in which duplicate dishes were assayed in triplicate for cyclic AMP. *Values represent the mean of duplicate dishes. Cyclic AMP determinations were done in triplicate for each sample.

Concomitant with the morphological changes, fucosylglycolipid metabolism was altered markedly after addition of cyclic AMP to the cold-sensitive transformants grown at 33 °C (unpublished results of K.D.S., and S. M. Steiner). It thus seems that this system provides an important exception to mechanisms currently postulated for the role of cyclic AMP in the expression of the transformed state. A solution to the difference between the cyclic AMP-mediated morphological transformation of NRK(MSV-1b) cells and what is usually observed in comparison of cyclic AMP levels and effects in transformed and non-transformed cells awaits the elucidation of the nature of the cold-sensitive transforming function present in cells transformed by the MSV mutant. Perhaps more importantly, the rapid acquisition of the transformed phenotype after exposure to cyclic AMP provides a useful model for studying the control of viral gene expression and should aid in the identification and characterisation of viral gene products responsible for malignant transformation.

Genetic heterogeneity in GM1-gangliosidosis

GM1-GANGLIOSIDOSIS is an inherited lysosomal storage disease which is due to a deficiency of the acid hydrolase GM1- β -galactosidase¹. During the past few years several clinical variants have been described²⁻⁶ that differ in time of onset of symptoms, involvement of visceral organs or skeletal tissue and in the degree of neuronal and mental deterioration. Some of these variants have been related to different properties of the deficient β -galactosidases^{5,7} but the significance of the experimental data⁸ has been questioned. Several investigators have speculated on the genetic background of the different variants^{2,8,9} but no experimental evidence has been provided to support the hypotheses.

Using somatic cell hybridisation techniques¹⁰⁻¹² we have investigated whether different gene mutations are involved in clinical variants of GM1-gangliosidosis. Fibroblasts from a patient with the infantile type 1 and the juvenile type 2 (refs 1-3), and from the type 3 patient without mental retardation described by Pinsky *et al.*⁵ were fused with cells from an adult (type 4) patient reported by our group⁶. Two days after hybridisation the occurrence of genetic complementation was tested by β -galactosidase assays with both synthetic and natural substrates. These experiments showed that the gene mutation in types 1 and 2 is different from that in types 3 and 4. Enzyme assays performed in single heterokaryons containing the genomes of type 1 and type 4 cells showed that genetic complementation results in complete restoration of normal enzyme activity.

Normal skin fibroblasts and cells from patients with the different types of GM1-gangliosidosis were grown in Ham F10 medium supplemented with 10% foetal calf serum and antibiotics. In homogenates of fibroblasts from patients with the type 1 or type 2 variant, β -galactosidase activity was less than 1% of control values when measured with the 4-methylumbelliferyl (MU) substrate. Homogenates of fibroblasts from patients with type 3 or type 4 GM1-gangliosidosis had a residual activity of 15-20%. In type 4 cells a 5% and 8% residual activity with the natural substrates GM1-ganglioside and asialofetuin was found by Dr J. S. O'Brien (Department of Neurosciences, University of California, La Jolla).

Cells from the adult type 4 patient were hybridised with those from the other three variants and each cell strain was also fused with itself (parental fusion) as a control. The results of β -galactosidase assays with synthetic substrate are shown in Fig. 1. Levels of activity in unfused cells were similar to those in the parental fusions, which indicated that somatic cell hybridisation did not affect enzyme activity. The β -galactosidase activities in fusions of type 1 \times type 2 and of type 3 \times type 4 cells remain unchanged relative to the average level expected in a mixture of equal numbers of parental cells. Fusion of type 1 \times type 4 cells, however, resulted in a six- to sevenfold increase in enzyme activity. Also there was a markedly increased enzyme activity in fusions of type 4 \times type 2 cells.

Similar results were obtained when the β -galactosidase activity was measured with the natural substrate GM1-

β -galactosidase activity
($\times 10^{-9}$ mol per h
per mg protein)

Fig. 1 β -Galactosidase assays on cell homogenates after fusion of cultured fibroblasts from patients with different variants of GM1-gangliosidosis. 2×10^6 cells from each strain were hybridised with inactivated Sendai virus¹³ under such conditions¹¹ that 50-80% of the nuclei were present in multinucleates. Two days after fusion cells were trypsinised, rinsed in saline and disrupted by sonication (2×30 s), and after protein analysis¹⁴ the β -galactosidase activity was assayed with 1 mM 4-methylumbelliferyl- β -D-galactopyranoside, pH 4.2, as described previously¹⁵. Independent experiments with the same cell strain; as controls three different normal strains were used; ———, expected enzyme activity if no complementation occurs, that is the mean enzyme activity as a result of mixing equal numbers of both parental cells.

ganglioside (Table 1). Conditions for cell cultivation, fusion, collection and protein determination were identical to those described in Fig. 1. Whereas no enzyme activity was detected after type 1 \times type 2 fusion a marked increase in GM1- β -galactosidase activity was observed after hybridisation of type 4 \times type 1 cells. An additional fusion experiment of type 4 \times type 1 cells was carried out with inactivated serum in the culture medium. This will inhibit proliferation of the unfused parental cells and thus the proportion of heterokaryons will be higher than if normal serum is used. This is reflected in the higher β -galactosidase activities in the last type 4 \times type 1 fusion shown in Table 1.

These results showed that genetic complementation had occurred in the fusion between type 4 cells and type 1 or type 2 cells. Thus the adult form of GM1 gangliosidosis (type 4 variant) is caused by a different gene mutation than is present in the types 1 or 2 variants. Since there was no complementation after fusion of type 4 \times type 3 cells these variants might be identical or determined by allelic mutations, as is the case for types 1 and 2 GM1-gangliosidosis¹⁷.

Although complementation could be detected by enzyme analyses in homogenates of heterokaryons it is not possible to evaluate the degree of restoration of activity since the proportions of nuclei from each parental cell present in the multi-

Table 1 β -Galactosidase assays using natural substrate after somatic cell hybridisation of different GM1-gangliosidosis variants

	Enzyme activity ($\times 10^{-9}$ mol per h per mg protein)	
	GM1- β -galactosidase	4-MU- β -galactosidase
Type 1 \times type 1	3.5	1.8
Type 2 \times type 2	4.3	4.0
Type 4 \times type 4	10.5	13.4
Type 1 \times type 2	<1	<1
Type 1 \times type 4	44.1	38.6
Type 1 \times type 4*	99.8	75.3
Control	193.8	246.7

*After fusion, cells were grown on medium with 10% foetal calf serum that had been treated with alkali (pH 10.7) for 3 h at 37 $^{\circ}$ C to destroy enzyme activity in the medium. Conditions of cell culture, hybridisation and collection were similar to those described earlier. GM1-galactoside- β -galactosidase activity was measured according to Ho *et al.*¹⁶.

nucleates are unknown. To solve this problem microchemical techniques were developed which facilitated quantitative enzyme assays in individual binuclear heterokaryons^{15,18}. Fibroblasts from the adult patient with type 4 GM1-gangliosidosis were hybridised with those from a type 1 variant under such conditions that about 8% of the hybrid cells are binucleate¹⁵. After fusion cells were grown for 24 h in a Falcon flask, they were then trypsinised and 2×10^4 – 4×10^4 cells were seeded in a dish with a thin plastic bottom. After 24–48 h of subsequent cultivation these dishes were frozen and freeze-dried immediately and small pieces of plastic each containing one binuclear cell or one non-fused mononucleate cell were dissected under microscopic control. β -Galactosidase assays in individual cells were carried out with synthetic substrate in submicrolitre volumes and fluorescence measurements were made in a microspectrofluorometer as described earlier^{15,18}.

The distribution of β -galactosidase activity in individual unfused control fibroblasts is shown in Fig. 2a. Results from three different cell strains were pooled, but also in cells from each cell strain there was a considerable variation of activity in the range 4×10^{-14} – 40×10^{-14} mol h⁻¹. In considering these data it should be realised that the enzyme activity is expressed per cell and that the total cellular dry mass and protein content in individual fibroblasts also show marked variations^{18,19}.

The mean β -galactosidase activity in control cell strains varied from 19×10^{-14} to 26×10^{-14} mol h⁻¹. Earlier experiments¹⁷ showed that the level of activity in parental fusions of control fibroblasts was approximately twice that of mononucleates. No β -galactosidase activity could be detected in

individual binuclear cells after parental fusions of type 1 cells while in parental fusions of type 4 cells mean activities of 3×10^{-14} and 5×10^{-14} mol h⁻¹ were found in two experiments; this is 10–20% of the activity in parental fusions of control fibroblasts (Fig. 2b).

After fusion of type 4 \times type 1 cells in 21% of the binucleates no β -galactosidase activity could be detected; these probably represent fusions of type 1 \times type 1 cells. In 27% of the binuclear cells the enzyme activity was similar to that in parental fusions of type 4 cells. But in 52% of the binuclear heterokaryons β -galactosidase activity was in the range 8×10^{-14} to 40×10^{-14} mol h⁻¹ (Fig. 2c). This is greater than in either of the parental cells before or after fusion and the range of activity is similar to that in mononuclear control fibroblasts. Thus genetic complementation after fusion of type 4 \times type 1 cells results in restoration of β -galactosidase activity to normal control levels.

The mechanism responsible for the genetic complementation observed after fusion of type 4 cells with type 1 or type 2 cells is not yet understood. In human liver two forms of GM1-ganglioside- β -galactosidases (A and B) have been identified^{16,20} both of which are deficient in GM1-gangliosidosis²⁰. It has been proposed that the A form of β -galactosidase consists of a single polypeptide chain²¹ and that the B form is a multimeric aggregate of the A monomer⁹. On this basis the results of our hybridisation studies would indicate the occurrence of intragenic complementation. In a recent review, O'Brien⁹ does not exclude the possibility that the B form of β -galactosidase also contains amino acid sequences which are not common to the A form. In that case the complementation in type 4 \times type 1 or 2 heterokaryons could still be intergenic. A third possibility is that the gene mutation in type 4 GM1-gangliosidosis involves a regulator whereas the mutations in type 1 and type 2 are structural mutations. The latter is supported by immunological studies^{9,22} which revealed the presence of cross-reactive material in cells from all patients tested with type 1 and type 2 GM1-gangliosidosis. Preliminary analyses of the deficient β -galactosidase in type 4 cells and cocultivation studies are suggestive for a regulator mutation in the adult type 4 GM1-gangliosidosis. Further investigations on the immunological and biochemical properties of the deficient enzyme and of the restored enzyme activity after genetic complementation are required to prove this hypothesis.

We thank Dr J. S. O'Brien for stimulating discussions and for the enzyme assays with GM1 ganglioside and asialofetuin. We thank Drs Pinsky and Goldman (Montreal), Willcox (London) and Niermeijer (Rotterdam) for cell material from their patients, and Dr I. Braidman for help in the preparation of the manuscript. This study was financed in part by The Netherlands Foundation for Medical Research and by a project grant from the Medical Research Council to M.W.H.

Influence of sexual dimorphism on foetal and placental weights in the rat

THE male is heavier than the female in the adults of most mammalian species. This trend is apparent at birth in humans¹ and in many other mammals including the sheep, goat, cow, rat and monkey². Little is known however, of the developmental basis for these birth weight differences. We have found that, one day before birth, male rat foetuses are 5% heavier than female foetuses, yet there seems to be no difference in the weights of their placentae.

Heavier foetuses are generally associated with heavier placentae³. This could be a causal relationship, where foetal growth is limited by placental function, as reflected by placental weight, or it may merely be a consequence of the common origin of the foetus and the foetal component of the placenta³. Whatever the reason, it might be expected that male foetuses would have heavier placentae than female foetuses. Here we examine the influence of sex on foetal and placental weights in the rat as part of a general study on the control of placental development and function. We have also tested the hypotheses that the sex of a conceptus has a general systemic effect on the growth of all other conceptuses in the litter and a local effect on its immediate neighbours since there is some evidence of similar effects in man⁴.

Thirty-four albino rats with a mean weight at mating of 238 ± 3 g (mean \pm s.e.) were used. The day spermatozoa were found in a vaginal smear was called day 1 of gestation. On day 22, the day before expected parturition, each rat was killed with an overdose of sodium pentobarbitone, its uterus removed and the number and position of all implantation sites recorded. The uterus was then opened and each conceptus examined in detail. Only 'live' foetuses, which moved in response to pressure, were included in the results. The sex of each foetus was determined by the distance between the anus and the genital tubercle (about 2 mm in males and 1 mm in females). The internal genitalia were examined in 25 of the foetuses and were always found to agree with the external morphology. The foetal membranes and umbilical cord were removed from each conceptus; the foetus and placenta were wiped dry and weighed separately.

There were 9.9 ± 0.6 live foetuses per litter: 49.7% were males. Thirty-four conceptuses, about one per litter, died at various stages before day 22. The mean foetal weight per litter was 4.598 ± 0.056 g, the mean placental weight was 0.463 ± 0.006 g and the mean foetal weight : placental weight ratio was 10.049 ± 0.220 .

In the rat, conceptuses in the middle of both uterine horns tend to be heavier than those at either end⁵. Any selective positioning of male and female conceptuses along the horn

could have caused this trend or alternatively, have affected any appraisal of differences in male and female weights. No selective positioning was apparent however, since the numbers of males and females were respectively 27 and 26 at the ovarian end, 20 and 30 at the middle and 20 and 29 at the vaginal end of the horns. Horns containing foetuses of one sex only were excluded.

Sex differences in conceptus weights were determined in each horn to avoid between rat and between horn variation. Male foetuses were found to be 5.4% or 0.247 ± 0.030 g heavier ($P < 0.001$, $n = 55$) than female foetuses. The placentae of male foetuses were however, only 1.3% or 0.006 ± 0.008 g heavier (not significant). The foetal weight : placental weight ratio was thus higher (5.2%, $P < 0.005$) in males than in females.

The systemic effect of the number of males and the number of females in the litter on mean foetal and placental weights was examined by analysis of covariance. Larger litters, irrespective of sex, had smaller placentae $r = -0.528$ ($P < 0.01$, $n = 34$). At equal litter sizes however, there was no apparent difference in the effect of the number of males or the number of females on mean placental or foetal weights of either sex.

The local effect on each foetus and placenta of the sex of its immediate neighbours was assessed by classifying each foetus as having either 0, 1 or 2 neighbours of the opposite sex and then comparing foetal and placental weights between these classes. Comparisons were made within each horn to avoid between horn variation, consequently the number of horns with examples of two or more of these classes was reduced. Conceptuses were excluded if their immediate neighbour was dead, since the dead conceptus could not be sexed and may, itself, have had a local effect.

Male conceptuses seemed to be little influenced by the sex of their neighbour although male foetuses and placentae with two female neighbours were 3.8% and 4.5% heavier (not significant, $n = 7$) than those without female neighbours. No other male class comparisons yielded differences of greater than 0.7%. There was more indication that female conceptuses were influenced by the sex of their neighbour. Female foetuses with one male neighbour were 2.9% heavier ($P < 0.05$, $n = 27$) than those without male neighbours. Placentae of female foetuses with two male neighbours were 6.5% ($P < 0.05$, $n = 9$) and 8.6% (not significant, $n = 4$) lighter than those with one or no male neighbours respectively. No other female class comparisons yielded differences of greater than 1.3%.

The principal finding to emerge from the above results was that male foetuses are about 5.4% heavier than females but their placental weights are remarkably uniform. Similar observations have been reported in the monkey³. These findings raise a number of questions about the developmental basis of sexual dimorphism.

Sexual differences in growth rates of conceptuses, either by cellular enlargement or by multiplication, can be attributed directly to a genotypic difference and indirectly to various environmental differences evoked by the genotype. It has been shown that even at the blastocyst stage, the genotype of the conceptus can affect its own growth rate⁶. In this way the XX or XY chromosome complement may have a differential effect on the growth rate of cells, irrespective of environmental influences. While there is no evidence as yet for such a genetic effect, male-female weight differences seem to depend on more than just hypothalamic or gonadal hormones since weight differences are evident even in anencephalic foetuses⁷. The latter would be expected to have low, if any, levels of these hormones, at least in the second half of gestation⁸. On the other hand, if the sex chromosome complement intrinsically affects cell growth or division in the foetus, it is difficult to explain why it did not affect the placenta, an organ largely composed of foetal tissue.

Environmental factors which might influence male-female weight differences include the interaction of the foetus with its mother and gonadal hormones. The degree of antigenic interaction of mother and foetus in mice can influence placental and subsequently foetal size⁹. Since male foetuses possess the

greater antigenic dissimilarity they might be expected to have heavier placentae⁴. Our placental weight findings would however, seem to discount this hypothesis. Gonadal hormones are often used to explain sexual dimorphism. They do affect the differentiation of the reproductive tract of the foetus, so they might also affect its growth rate. The evidence of the anencephalic children however, tends to oppose this idea. In addition, if male gonadal hormones, generally considered to be anabolic, affect foetal growth, why do they not affect placental growth? Perhaps the placenta is not a target for gonadal hormones or, if it is, it may respond by improved efficiency rather than by weight. Differences in the efficiency of the placenta or of the foetus to use its placenta could mask any association of foetal and placental weights expected if foetal growth is indeed limited by placental function at the level of sexual dimorphism.

The possibility that each foetus, depending on its sex, releases or evokes circulating substances in its mother, that in turn affect the growth rates of other foetuses in the litter, was not supported by any evidence of systemic effects. On the other hand, it did seem that the sex of a foetus can influence the growth rates of its neighbours, presumably by releasing or evoking locally acting substances. Although this finding requires confirmation, there is good evidence that other hormones, notably prostaglandins, are produced in the uterus and have powerful local effects extending even to the ovary¹⁰.

In the rat and several other mammals, sexual dimorphism in relation to size is apparent even before birth. A closer examination of this phenomenon and its ramifications may well lead to a better understanding of the control of prenatal growth.

Prolactin levels and duration of postpartum anoestrus in lactating ewes

THE length of the postpartum anoestrous period in sheep is related to the degree of mammary stimulation. If the ewe is milked by hand twice a day or 'dried off' immediately after parturition, the first oestrus occurs 30-40 d postpartum in the 'Préalpes du Sud' breed; if the ewe is nursing her lamb(s)—suckling 10-12 times per day—postpartum anoestrus lasts for 60-80 d (ref. 1). A similar phenomenon has been described in women; menses reappear within 10 weeks postpartum in 80% of women who are not breast feeding, but in only 10% of those who are². In both species suckling is accompanied by large discharges of oxytocin and prolactin; this reflex secretion of prolactin decreases as lactation progresses, and is almost nonexistent by the time of return of cyclical ovarian activity.

Amenorrhoea is also associated with high blood levels of

prolactin in women who are not breast feeding, and menses return after the prolactin levels have been lowered by hypophysectomy or administration of a prolactin-suppressing drug like 2-bromo- α -ergo-cryptine³.

These facts all suggest that prolactin has an antigonadal action^{4,5}; we have therefore studied ovarian and pituitary activity in lactating ewes after denervation of the mammary gland to inhibit the afferent arc of the suckling reflex. Denervation can be achieved by several means⁶. Bilateral section of dorsal pathways of the spinal cord at T₁₁, and bilateral sympathectomy and section of the perineal nerves results in a disappearance of the normal prolactin surge observed during milking or suckling. A similar effect is observed after the bilateral section of the afferent roots of lumbar nerves 1, 2, 3 and 4, lumbar sympathectomy, and section of the perineal nerves. Unilateral section of the afferent nerves from the mammary gland shows that the spinal reflex resulting in a prolactin surge after teat stimulation is ipsilateral (Fig. 1).

Fig. 1 Prolactin levels in suckled ewes before and after unilateral severance of lumbar nerves 1, 2, 3 and 4. Results expressed as ng ml⁻¹ (NIH, PS7). a, Reflex prolactin secretion triggered by suckling (arrow) in a normal ewe; b, after unilateral mammary denervation; b₁, disappearance of reflex prolactin secretion after ipsilateral teat stimulation (arrow); b₂, restoration of the reflex on contralateral teat stimulation (arrow).

All nervous connections between the mammary gland and the body were severed, including perivascular sympathectomy of the inguinal blood vessels, in five 'Préalpes du Sud' ewes during late pregnancy. After normal parturition, ewes were allowed to suckle their lambs, as were eight unoperated control ewes, which lambed at the same time. Blood samples were obtained twice daily for radioimmunoassay of prolactin and luteinising hormone (LH)^{7,8}, and oestrous behaviour was checked after blood sampling using a vasectomised ram. Laparoscopy was carried out on all the ewes between days 12-15, 25-31 and 40-50 postpartum to examine the state of the ovaries.

The normal prepartum surge of prolactin secretion and the

basal levels during lactation were unaffected in the denervated animals, but the suckling stimulus of the lambs was not followed by the normal reflex discharge of prolactin. As in previous experiments⁶, the growth of the lambs of these denervated ewes was normal.

In control animals, neither ovulation nor an LH peak was observed before 25 d *postpartum*; five of the eight animals exhibited silent ovulations preceded by an LH surge between days 25 and 50 *postpartum*, and only three of them came into oestrus during this period. In marked contrast, three of the five operated animals had ovulated without showing oestrus before day 14 *postpartum*, and all five animals had ovulated and shown oestrus before day 50.

These results establish that it is the suckling stimulus, and not lactation itself, that in some way suppresses the resumption of cyclical ovarian activity. In preliminary experiments we have been able to show that pharmacological suppression of prolactin secretion in suckling ewes with 2-bromo- α -ergocryptine (CB154, Sandoz) is also followed by an early restoration of cyclical ovarian activity⁹. Therefore it seems reasonable to conclude that it is the surges of prolactin secretion specifically induced by suckling that are in some way responsible for the suppression of ovarian activity during lactation.

We thank Dr R. V. Short for criticism and Mrs C. Meusnier and J. Paly for technical assistance.

Structure of DNA molecules in yeast meiosis

THE nuclear DNA of the yeast *Saccharomyces cerevisiae* has been the subject of a detailed electron microscopic examination^{1,2}. These studies have revealed long, continuous molecules of lengths up to 355 μm , which correspond to the molecular weights of nuclear DNA estimated from sedimentation analysis in sucrose gradients. Several replication structures (bubbles) were observed along single molecules^{2,3}, as found in other eukaryotes^{4,5}. The most useful observations were made on selected replicating DNA³ and on DNA of mutants that were arrested just after the initiation of DNA synthesis⁶. We have started to study the structure of DNA molecules during meiosis because of its direct relevance to the process of recombination. Models to explain recombination (for review see ref. 7) are based mostly on genetic data from meiotic analysis, among which yeast tetrads occupy an important position. The various models have molecular implications which could best be tested by the direct examination and quantification of the interactions among DNA molecules, and between DNA and proteins, during meiosis.

Three unique features are expected to characterise meiotic DNA. First, the longer duration of the premeiotic DNA synthesis may be the result of the presence of fewer replicons than in the vegetative replication, as found in *Triturus*⁸. It has also been suggested that certain regions remain unreplicated during the premeiotic S period and are completed only during zygotene⁹. The second unique feature of meiotic DNA inter-

actions is pairing; the four double helix molecules that constitute the four chromatids of a bivalent (provided one accepts the unine structure of the chromatid⁹) must be paired intimately. The third feature, breakage and reunion between the paired molecules, is expected from the genetic data to occur 5–15 times along an average-sized bivalent of yeast¹⁰. This is the act of recombination itself, based probably on base pairing between antipolar single-stranded molecules from different chromatids. Depending on the model⁷, single-stranded regions either remain in the backbone of the DNA molecules (chromatids), and are later repaired by polymerase and ligase, or they remain projected from the double-stranded molecules and are later digested by exonuclease/ligase repair activity.

Vegetative cells of strain 419/1 that were labelled with ³H-6-uracil as described in the legend to Fig. 1, were transferred to sporulation medium (SPM) to give meiosis with kinetics

Fig. 1 Pairing between two DNA molecules. These molecules were paired over a length of 30 μm and were clearly connected to each other in at least two other places. The threads linking the two molecules here are probably single-stranded, at least over part of their length. DNA was prepared for electron microscopy by a modified Kleinschmidt technique¹⁴. The diploid yeast strain 419/1 is a *ura1/ura1* homozygous derivative (obtained after low-dose ultraviolet irradiation) of strain 419 (ref. 11). DNA was prepared from meiotic cells for equilibrium sedimentation analysis after they were grown overnight at 30 °C in PSP2 medium¹² supplemented with adenine (40 $\mu\text{g ml}^{-1}$), uracil (20 $\mu\text{M ml}^{-1}$) and ³H-6-uracil (3 $\mu\text{Ci ml}^{-1}$, specific activity of label 13.6 Ci mM^{-1}), to a titre of 10⁷ cells ml^{-1} and were washed and resuspended in SPM for 6.75 h. Spheroplasts were prepared from 5 ml of the culture by 30-min incubation with Glusulase (Endo Lab.) in spheroplasting buffer¹³, lysis was obtained following their transfer to a lysis buffer¹³, and the lysate was mixed with a saturated solution of CsCl, to a volume of 5 ml, with an average buoyant density of 1.690 g ml^{-1} . Density gradients were obtained in cellulose nitrate tubes following 60-h runs in the Spinco type 50 rotor at 35,000 r.p.m. The tubes were pierced and dripped into 35–40 tubes, from which samples were counted for radioactive label, following an overnight alkali treatment (NaOH 0.5 N) and TCA precipitation (BSA added as carrier). The nuclear DNA was separated from the mitochondrial DNA by about 12 fractions, the former giving a very sharp peak of 2–4 fractions, from which DNA was spread for the electron microscopy. Samples (10 μl) were taken from the nuclear peak fractions of the CsCl gradients. The DNA concentration in these fractions was estimated to be about 1–2 $\mu\text{g ml}^{-1}$. Each sample was added to 30 μl of a freshly prepared mixture, containing 0.1 mg ml^{-1} cytochrome c, 3 M ammonium acetate buffer (pH 6.8) and 50% formamide. After gentle agitation, 5 μl were withdrawn and spread, in a wax-coated depression plate, on a 1-ml hypophase containing 0.3 M ammonium acetate buffer (pH 6.8) and 10% formamide. A carbon-coated grid was used to pick up a small drop from the hypophase surface. The grid was then dehydrated in absolute ethyl alcohol and shadowed with platinum–palladium (80:20) at an angle of 10° in vacuum of 5×10^{-5} mmHg. A JEOL-JEE 4B high vacuum evaporator with a rotatory table (60 r.p.m.) was used for the shadowing. A JEOL 7A electron microscope was used, with 40- μm foil objective aperture and 80 kV accelerating voltage. Magnification was calibrated with a carbon grating replica, 28,800 lines per inch (Ernest F. Fullam, Inc., Schnectady, New York). DNA control standards were *Herpes simplex* type 1 DNA (mean length $54.3 \pm 0.3 \mu\text{m}$) and $\phi\text{X174 RF}$ DNA (mean length of $1.8 \pm 0.3 \mu\text{m}$) that were received from Y. Shlomai and A. Razin, respectively. Bar represents 0.5 μm .

slightly faster than in related strains^{11,12}: the premeiotic DNA synthesis took place between 4 and 7 h, the first meiotic division took place at about 8 h, recombination commitment (ADE colonies) was from 5 to 8 h and haploidisation was from 7 to 9 h. The short duration of each meiotic stage and the asynchrony in the culture (estimated to be 2–3 h) resulted in a notable degree of overlapping between the premeiotic replication and the early meiotic stages.

Vegetative DNA spreads, prepared from the nuclear peaks of CsCl gradients, appeared in the electron microscope to be similar in every respect to the molecules described by Petes *et al.*^{1–3}. Linear molecules were of various lengths up to 300–400 μm . A few molecules were in replication, with 'bubbles' ('eye-forms') of various lengths. We also observed small circular molecules, 2 μm in circumference, as described previously¹⁵. Some of these small molecules were supercoiled and a few were replicating, showing a closed, symmetrical, bacteria-like replicon.

Fig. 2 Parts of linear double-stranded molecules with two single-stranded projections each. *a*, The lengths of the projections are 1.0 and 0.8 μm and the intermediate region (between the branching off points of the projections) is 0.2 μm ; *b*, the lengths of the projections are 1.16 and 0.28 μm and the intermediate region is 0.1 μm . Bars represent 0.5 μm .

Meiotic DNA spreads were prepared from samples taken at 5, 6, 6.75, 7.5 and 8 h in sporulation. At the two earliest times, we observed 'bubbles' of various sizes, including some much longer than those found in vegetative DNA. These molecules could, however, be paired molecules that were merged over short distances. As yet we find it difficult to resolve with certainty very long 'bubbles' from paired molecules. Paired molecules were also common in our preparations from 6 h onwards, including pairing arrangements of three and four molecules (see, for example, Fig. 1). Comparable pairing configurations were not observed in any of our vegetative DNA preparations.

The most characteristic feature of the meiotic DNA molecules were single-stranded projections observed quite commonly in the 6-h preparation and with higher frequency in the 6.75-h preparation. The projections usually occur in pairs (Fig. 2) and

sometimes they appear repeatedly along the same molecule. In most cases, the single-stranded projections seem quite convincingly to be an integral part of the main double-stranded molecule. We did not see such single-stranded projections in the vegetative DNA preparations, nor did we see them on the 2- μm circles in the meiotic DNA preparations. (The circles in the vegetative and meiotic preparations had a similar appearance.) In some preparations there seemed to be a certain affinity between the single-stranded projections of different molecules, resulting in complex configurations. At this preliminary stage, we cannot resolve these, or other complex molecules.

Fig. 3 Two possible interpretations of the molecule in Fig. 2a.

The pairs of single-stranded projections are most easily interpreted as the simplest recombination, or gene conversion, configurations outlined in Fig. 3. We believe these projections to be the result of genetic recombination, but we cannot exclude the possibility that they are intermediate structures towards the act of recombination. If, however, the former interpretation is correct, and Fig. 3 is taken at face value, the length of the heteroduplex region that resides between the two projections can be estimated. In Fig. 2a, this length is approximately 0.2 μm and in other pairs of projections the length of the intermediate region was found to be between 0.1 and 0.5 μm . The heteroduplex region in Fig. 2a is about 600 nucleotides long, and this corresponds well with the length estimated from genetic data on coconversion in yeast¹⁶.

Electron microscopic analysis of the structure of meiotic DNA can aid the understanding of genetic recombination at the molecular level and the choice between the various proposed models⁷. Our experience with this material, however, has convinced us that a systematic study of the variety of configurations encountered can only be made if accompanied by the use of mutants or treatments that accumulate intermediate configurations. As no true *rec⁻* mutants are available in yeast, we are now studying DNA structure in the *cde* mutants¹⁷, which block meiosis¹¹ at defined stages of DNA synthesis or nuclear division.

Major mRNA species from spinach chloroplasts do not contain poly(A)

POLY(A) is a constituent of most animal cytoplasmic mRNAs^{1,2} and has been demonstrated in rapidly-labelled, polysomal RNA in plants^{3,4}. Verma *et al.*⁵ have shown that cellulase mRNA, isolated from auxin-treated pea epicotyls, contains poly(A). Although a significant proportion of eukaryotic polysomal mRNAs are known to lack poly(A)^{6–8}, the presence of poly(A) is still regarded as a characteristic feature of unfractionated preparations of eukaryotic mRNA. By contrast, poly(A) has not been detected in mRNA from prokaryotic cells⁹. Several reports^{9–11} have indicated that poly(A) is present in HeLa cell mitochondrial RNA, although Groot *et al.*¹² were unable to detect poly(A) in yeast mitochondrial RNA. Here we describe experiments in which we have assayed for the presence of poly(A) in spinach chloroplast RNA by two methods; (1) hybridisation of chloroplast RNA with ³H-poly(U) and (2) binding of chloroplast RNA, pulse-labelled *in vivo*, to oligo(dT) cellulose. Additionally, the mRNA activities of chloroplast poly(A)-containing RNA and non-poly(A)-containing RNA (hereafter referred to as poly(A)⁺ RNA and poly(A)[−] RNA respectively) have been investigated by measuring their translation into specific polypeptides in cell-free extracts from *Escherichia coli*. From the results, we conclude that chloroplast mRNA lacks poly(A).

isolated from leaves labelled *in vivo* for 3 h with ³²P-ortho-phosphate¹⁴. For comparison of poly(A)⁺ RNA content, leaf total RNA was prepared from the same tissue. We have previously shown¹⁴ that in leaves pulse-labelled with ³²P-ortho-phosphate for 3 h, label is incorporated into mature rRNA, rRNA precursors and 'polydisperse' RNA in both chloroplast and leaf total RNA preparations. The poly(A)⁺ RNA content of the samples was determined by fractionation on columns of oligo(dT) cellulose as described by Clegg and Kennedy¹⁵. The results (Table 2) show that whereas 10.5% of the leaf total labelled RNA is retained by oligo(dT) cellulose, and is subsequently eluted in low salt buffer, only 2.1% of the RNA extracted from the crude chloroplast preparation is thus retained by oligo(dT) cellulose. A significant proportion of the poly(A)⁺ RNA extracted from the crude chloroplast preparation probably represents cytoplasmic contamination, since washing the chloroplasts once with isotonic medium before nucleic acid extraction reduces the poly(A)⁺ RNA content to about 1%; washing the chloroplasts a second time does not further reduce the poly(A)⁺ RNA content. Polyacrylamide gel electrophoresis of the ³²P-labelled poly(A)⁺ RNA fraction in leaf total RNA showed it to be heterogeneous in size, ranging from 0.2 × 10⁶ to 4 × 10⁶ molecular weight (not shown). In contrast, the poly(A)⁺ RNA from washed chloroplasts was much smaller in size, the majority migrating ahead of 4S RNA. This suggests that the small amount of poly(A)⁺ RNA in the washed chloroplast preparation does not simply arise from cytoplasmic contamination.

To establish whether or not it is the small amount of chloroplast poly(A)⁺ RNA, or the poly(A)[−] RNA which possesses mRNA activity, the two fractions were assayed for their ability to direct the synthesis of specific polypeptides in a cell-free protein synthesising system from *E. coli*. The products of cell-free protein synthesis were analysed by polyacrylamide gel

Table 1 Determination of poly(A) content by hybridisation with ³H-poly(U)

Source of RNA	Amount (μg)	RNase-resistant c.p.m.	c.p.m. minus no RNA control	Poly(U) in hybrid (μg)	% poly(A)
No RNA	—	87	—	—	—
<i>E. coli</i> ribosomes	50 100	78 83	—	—	ND ND
Bacteriophage MS2	50 100	350 608	263 521	0.0018 0.0036	0.0034 0.0034
Spinach leaf (total)	50 100	6 153 11,362	6,066 11,275	0.043 0.079	0.080 0.074
Spinach chloroplasts	50 100	330 621	243 534	0.0017 0.0037	0.0032 0.0035

Hybridisation mixtures contained the components of the standard assay described by Gillespie *et al.*¹³ 50 or 100 μg of the non-radioactive RNA shown and 1 μg of ³H-poly(U) (specific activity 143 × 10³ c.p.m. μg^{−1}; prepared as described by Eaton and Hutchinson¹⁶) in a total volume of 125 μl. After incubation at 36 °C for 24 h, 2.5 ml of 0.5 M NaCl, 10 mM MgCl₂, 10 mM Tris-HCl (pH 7.2) was added, followed by 15 μg RNase A and 5 μg DNase I, and incubation continued at 30 °C for 1 h. TCA-insoluble radioactivity was determined as described by Gillespie *et al.*¹³. The poly(A) content of the RNAs was calculated from the equation: poly(A) content = (μg hybrid poly(U) × 0.933)/(μg RNA) × 100. Spinach leaf total RNA, chloroplast RNA and bacteriophage MS2 RNA were prepared as described previously^{14,15}. *E. coli* rRNA was described by Avery¹⁷.

ND, Not detectable.

Samples of spinach chloroplast RNA were assayed for their poly(A) content by hybridisation with excess ³H-poly(U) in conditions reported to be optimal for poly(A)-poly(U) hybrid formation¹³. For comparison, samples of leaf total RNA (presumably containing poly(A) tracts), *E. coli* rRNA and bacteriophage MS2 RNA (the latter two lacking poly(A) tracts¹³) were similarly analysed. The results (Table 1) show that the poly(A) content of chloroplast RNA (0.003%) is some 25 times less than that of leaf total RNA, and is nearly identical to that of MS2 RNA (Table 1).

To investigate the poly(A)⁺ RNA content of pulse-labelled chloroplast RNA, RNA was extracted from chloroplasts

electrophoresis. The gel profiles obtained (Fig. 1) show that the product synthesised in the presence of chloroplast poly(A)[−] RNA (Fig. 1a) contains two discrete radioactive polypeptides of molecular weights 52,000 and 35,000. We have reported previously a very similar pattern of incorporation directed by unfractionated spinach chloroplast RNA, and established the identity of 52,000 molecular weight product as being the large subunit of Fraction I protein¹⁵. The identity of the 35,000 molecular weight product is at present unknown. The product synthesised in the presence of poly(A)⁺ chloroplast RNA (containing additionally 100 μg *E. coli* rRNA as carrier) contains no discrete, high molecular weight polypeptides

(Fig. 1b) and is qualitatively and quantitatively similar to the product synthesised in the presence of 100 μ g *E. coli* rRNA alone (Fig. 1c). From these results we conclude that the mRNAs for the large subunit of Fraction I protein and the 35,000 molecular weight polypeptide lack poly(A) tracts. This does not entirely exclude the possibility that other chloroplast mRNAs may contain poly(A), since they could be translated with a low efficiency in the *E. coli* cell-free system. This possibility is unlikely, however, since the products of incorporation directed by poly(A)⁻ RNA are qualitatively similar to those synthesised in intact, isolated chloroplasts¹⁵.

The most likely explanation of the results described here is that spinach chloroplast mRNA lacks poly(A); tracts of less than about 20 adenylate residues would not have been detected². In view of the complete lack of knowledge surrounding the

Fig. 1 Gel electrophoresis of the products of chloroplast poly(A)⁺ and poly(A)⁻ RNA-directed protein synthesis in cell-free extracts from *E. coli*. Chloroplast RNA was prepared as previously described¹⁴ and 0.5 mg aliquots separated into poly(A)⁺ and poly(A)⁻ RNA fractions on oligo(dT)-cellulose columns¹⁸. The poly(A)⁻ RNA, which passed through the column in 100 mM LiCl, 1 mM EDTA, 0.1% SDS, 50 mM Tris-HCl (pH 7.5) was ethanol precipitated directly from the eluant. The poly(A)⁺ RNA, eluted in low salt buffer (see legend of Table 2) was made 100 mM in NaCl; 100 μ g *E. coli* rRNA was then added as carrier before ethanol precipitation. A sample containing 100 μ g *E. coli* rRNA was similarly treated to serve as a control. These RNA samples were assayed for their ability to direct protein synthesis in *E. coli* S-30 extracts by methods previously described¹⁵. Products were analysed by SDS-polyacrylamide gel electrophoresis¹⁵. *a*, Incubation mix contained poly(A)⁻ RNA; *b*, incubation mix contained poly(A)⁺ RNA; *c*, incubation mix contained 100 μ g *E. coli* rRNA. —, Absorbance at 620 nm; histogram, radioactivity. LSU and SSU refer to the large and small subunits respectively, of Fraction I protein added to sample (*a*) as marker.

Table 2. Fractionation of pulse-labelled RNA on oligo(dT) cellulose columns

Source of ³² P-labelled RNA	Radioactivity applied to oligo(dT) cellulose column (c.p.m.)	Radioactivity eluted in low salt fraction (c.p.m.)	Poly(A) ⁺ RNA content (%)
Leaf (total)	50 × 10 ⁴	52,676	10.5
Crude chloroplasts	25 × 10 ⁴	5,251	2.10
Chloroplasts washed × 1	25 × 10 ⁴	2,623	1.05
Chloroplasts washed × 2	25 × 10 ⁴	2,717	1.09
<i>E. coli</i> ribosomes	100 × 10 ⁴	212	0.021

Leaves (5 g) excised from 15-d-old spinach plants were labelled for 3 h with ³²P-orthophosphate by way of their petioles¹⁴. Leaf total nucleic acid and crude chloroplasts were prepared¹⁴; for washed chloroplasts, the crude chloroplast pellet was resuspended in 5 ml of 0.35 M sucrose, 2 mM EDTA, 2 mM sodium isoascorbate and repelleted by centrifugation at 2,500g for 2 min. Chloroplast nucleic acid was prepared by the phenol-detergent method¹⁴. Ethanol-precipitated nucleic acid samples were dissolved at a concentration of 1 mg ml⁻¹ in 50 mM MES-NaOH buffer (pH 7.0), 2 mM MgCl₂ containing 5 μ g ml⁻¹ DNase I (RNase-free) and the samples incubated on ice for 20 min. Sodium dodecyl sulphate was then added to 0.5% and low molecular weight ³²P-labelled contaminants and DNase digestion products removed by exclusion chromatography on Sephadex G-25 columns. RNA samples were separated into poly(A)⁺ and poly(A)⁻ fractions on temperature-controlled oligo(dT)-cellulose columns as described by Clegg and Kennedy¹⁸. Poly(A)⁺ RNA was eluted from oligo(dT) cellulose with low salt buffer (10 mM Tris-HCl (pH 7.5), 0.1% SDS). The recovery of the radioactivity applied varied from 98% to 105%. ³²P-labelled *E. coli* rRNA was prepared as described by Avery¹⁷. Approximate specific activities of RNAs; leaf total, 4.1 × 10³ c.p.m. μ g⁻¹; chloroplast 2.3 × 10³ c.p.m. μ g⁻¹; *E. coli*, 34 × 10³ c.p.m. μ g⁻¹.

function of poly(A) in eukaryotic cytoplasmic mRNAs, no general significance can be placed on this finding at present, but it does reinforce the conclusion that poly(A) is not essential for messenger function^{19,20}. If the lack of poly(A) in chloroplast mRNAs proves to be a general phenomenon, it will be another respect in which chloroplasts resemble prokaryotes.

Auxin, carbon dioxide and hydrogen ions

HYDROGEN ions can partially mimic the effect of indoleacetic acid (IAA) on plant cell elongation¹. This observation has been elaborated in a proposal that the initial action of IAA causes the activation of a proton pump at the cell membrane. The pumping of protons would cause a lowering of the pH at the cell wall, leading to wall loosening². This proposal has been supported in studies in which the pH of the medium surrounding oat coleoptile³⁻⁵ or etiolated pea stem⁶ sections was observed to drop when auxin was applied. This acidification was most pronounced when tissue sections were used from which the epidermis with the cuticle had been peeled off³, and was presumed to be caused by the proton pump activated by IAA.

An increase in cell respiration occurs when tissues respond to exogenous IAA (ref. 7). The IAA-induced pH drop observed in the solutions surrounding peeled tissue sections may be attributable to increased leakage of CO₂ from the tissue and subsequent formation of carbonic acid. To investigate this possibility, we measured CO₂ concentrations in the solutions surrounding pea epicotyl sections challenged with IAA.

Pea seeds (*Pisum sativum* L. cv. Alaska, lot 401 from Burpee Seed Co., Riverside, California) were germinated in the dark at room temperature (21 °C). Subapical 10-mm sections from the third internode were cut from 8-d-old seedlings. In peeled section experiments, the epidermis with cuticle was removed with fine forceps³. After the experimental period, the section lengths were measured, the pH of the medium taken, and the CO₂ contents of the solutions were measured with a Natelson model 600 microgasometer (Scientific Industries, Springfield, Massachusetts), which manometrically measures CO₂ in solutions.

Table 1 Effect of IAA on pH and CO₂ in the solution surrounding etiolated pea stem sections*

Conditions	pH ± s.d.	mM CO ₂ ± s.d.	Calculated pH
Unpeeled	6.04 ± 0.09	1.6 ± 0.09	6.02
Unpeeled + IAA	5.81 ± 0.10	3.8 ± 0.06	5.73
Peeled	5.87 ± 0.08	1.9 ± 0.09	5.97
Peeled + IAA	5.45 ± 0.11	5.3 ± 0.56	5.45
No sections	6.30 ± 0.00	0.5 ± 0.12	6.15

*Prepared sections were stirred in 200–300 ml 1.0 mM KH₂PO₄ buffer, pH 6.25 for 150–200 min. Rinsed sections were divided into lots of 45 and placed in 50 ml beakers containing 5 ml 1.0 mM KH₂PO₄ buffer, pH 6.30. After 30 min, the initial pH reading was taken and IAA was added to 10 µM. Beakers were sealed with Parafilm and allowed to stir for 3 h at which time readings were taken³.

Measurements of pH showed that IAA induced some acidification in the solution surrounding unpeeled sections, but that the acidification was more pronounced when peeled sections were used (Table 1). These data confirm previous results reported for unpeeled⁶ and peeled³ sections. The CO₂ measurements showed that when there was a drop in pH, there was also a rise in the CO₂ content of the solution. Using a *K_a* for total CO₂ in solution of 4.2 × 10⁻⁷ and a *pK_a* for the buffer used of 7.2 we were able to calculate the pH of the solution expected if only CO₂ was involved in the acidification⁸. These calculated pH values (Table 1) are quite similar to the measured pH, indicating that dissolved CO₂ was probably responsible for the IAA-induced pH reduction.

We carried out a time-course experiment to further examine the correlation between dissolved CO₂ and reduction in pH. When peeled sections were exposed for varying times to IAA, the results confirmed the correlation between increases in CO₂ and decreases in pH in the surrounding medium. Once again,

Table 2 Time course of pH and CO₂ changes in solution surrounding IAA-treated etiolated pea stem sections

Hours in IAA	pH	mM CO ₂	Calculated pH
0	6.1	0.5	6.15
1	5.8	3.4	5.73
2	5.6	4.4	5.63
3	5.3	5.8	5.43

the CO₂ effect was calculated to be adequate to account for the pH drop observed (Table 2).

To determine the relationship between the two correlated phenomena in solution, we carried out experiments in flasks with KOH-soaked filter paper in a centre well with the sections and solution surrounding the well. As the KOH would neutralise any CO₂-caused acidification, any pH reduction would then be caused by other phenomena. That little pH reduction was observed in such an experiment (Table 3) suggests a cause and effect relationship between increased CO₂ and reduction of pH during IAA treatment. It has been shown that exogenous CO₂ increases can induce cell elongation⁹. In all of our experiments, cell elongation (approximately 2 mm in 3 h) occurred only in IAA-treated tissue.

Table 3 Effect of KOH-soaked paper in a centre well on pH and CO₂ in solution surrounding etiolated pea stem sections*

Conditions	pH ± s.d.	mM CO ₂ ± s.d.	Calculated pH
Unpeeled	6.15	1.2	6.06
Unpeeled + IAA	6.11 ± 0.09	1.1 ± 0.08	6.07
Peeled	6.15	1.4	6.04
Peeled + IAA	6.09 ± 0.10	1.3 ± 0.09	6.04

*Sections were treated as described in Table 1, except that the experiment was run in a flask with a centre well, containing filter paper soaked with 10% KOH or water (control).

The source of the increased CO₂ in our experiments is probably increased cell respiration induced by IAA, the gas dissolving to form carbonic acid, which dissociates into bicarbonate and hydrogen ions. Plant cuticles are generally impervious to CO₂, and consequently the pH drop in the solution would be expected to be more pronounced in peeled than unpeeled section experiments¹⁰.

Our data tend to negate the hypothesis that the pH drop observed in the solutions surrounding IAA-treated tissue is attributable to a direct pumping of protons^{3,4}. It is possible that bicarbonate is a counter ion which accompanies hydrogen ion secretion. The data do not rule out the possibility that the primary event in cell elongation is indeed a lowering of the pH at the cell wall.

We thank the chemistry laboratory at the Pomona Valley Hospital for use of the microgasometer, and Drs J. Bonner, D. Rayle, R. Cleland and P. van Eikeren for discussion.

matters arising

Interarc spreading in the Carpathian area

BOCCALETTI and GUAZZONE (ref. 1) have invoked the interarc spreading hypothesis to explain the genesis of the present structure of the Mediterranean area. We consider it necessary to clear up some fundamental points regarding one of the sectors they discussed.

The area inside the Carpathian Bend (including the Transylvania Basin in Rumania) was presented by Boccaletti and Guazzone as an interarc basin, the front and back inarc parts of which would be the Neogene volcanic zones in the East Carpathians and Apuseni Mountains. Because such a hypothesis has so far not been examined and argued but only stated²⁻⁴ we point out here the main geological facts which must be considered.

First, the basement of the Transylvanian Basin comprises both metamorphic and igneous (pre-Cenomanian) rocks, similar to those in the Carpathians⁵. Second, the sedimentary undeformed cover includes Palaeogene and early Miocene deposits continuous over large areas⁵. Third, there have so far been no observations indicating anomalous heat flow in this area.

The first point precludes any interpretation of the Transylvanian area as an interarc basin. If, however, this evidence were not considered, the second point would preclude a late Miocene age for the spreading process. Nevertheless, if the spreading were of that age, the Transylvanian Basin, being younger than the Pannonian Basin, should have a higher or comparable heat flow to that of the latter.

Finally, we emphasise that Karig⁶ developed the idea of interarc spreading for volcanic island arcs; his hypothesis cannot, however, be extended indiscriminately to apply to continental areas such as that inside the Carpathian Bend.

DRS BOCCALETTI AND GUAZZONE REPLY

—The structural model comprising a consuming (or contracting) zone, a folded arc, a magmatic arc, and spreading (or distended) zones, after Karig's formulation¹ and after additional ideas by Dickinson² and Dewey *et al.*^{3,4} must be considered the best model to date for investigating fossil continental margins, both in wide, contracting palaeo-oceans and in small, contracting palaeomarginal basins. Differences between oceanic and continental arcs are probably only a matter of differences in the ages of the contracting processes and differences in the dimensions of contracting areas. Consequently, different stages of maturity probably also occur in areas beyond the arcs.

In that sense all Mediterranean basins, both present and fossils, are very different from those of the western Pacific. Even the Tyrrhenian Basin, which is generally accepted as a typical marginal basin in the Mediterranean area (with active subduction, typical polarity and migration, and typical folded and magmatic arcs) also shows a crustal substratum that is strongly thinned and very hot. It seems to be complicated, however, by many sialic microfragments and sialic seamounts. These sialic 'lenses' are probably actual examples of a segmentation stage in the pre-Tyrrhenian crust. The original floor of the Tyrrhenian Sea, as well as the substrata of the other Mediterranean basins, was never entirely substituted by typical oceanic crust.

The points raised by Radulescu and Sandulescu⁵ can be explained as effects of a low level of maturity of evolution in the Carpathian arc-trench system, where the back-arc crust has been distended, thinned and in places fragmented to a certain degree. In fact, Tortonian sediments directly overlie the basement in many places of the Transylvanian Basin⁶. Some spreading may occur under cover, caused by discontinuous subduction; perhaps that can be

correlated with rotated arc migration. Incidentally, the age of the oldest deposits contemporaneous with the spreading in the basin must be related to later surface volcanism.

Stegena⁷⁻⁸ suggest that the inter-Carpathian area should be considered to be "warm". Comparisons between the Pannonian and Transylvanian basins could not give the same result if the directions of the investigation profiles are changed. In fact, it has been clearly demonstrated that the northern Carpathians are inactive whereas the south-eastern Carpathian Arc is still active⁹. Geothermic correlations between different basins should take into account the different thicknesses of their covers. The only conjecture that we can advance about the comparison between the Pannonian and Transylvanian basins is that the second is probably less 'mature' than the first.

LSD and dopamine receptors

PIERI *et al.*¹ reported a circling behaviour response to LSD in rats with unilateral chemical lesions of the ascending medial forebrain bundle. They used two rotational models; one was produced by 6-hydroxydopamine injection and the other by 5,6-dihydroxytryptamine injection. The factor common to both models was a deficit of dopamine in the ipsilateral forebrain. The authors demonstrated strong maximal contralateral turning responses to LSD given in a dose range of 0.1-1.5 mg kg⁻¹. Only the time course of turning seemed to be dose dependent.

We have repeated these experiments in similar animal models and have found the effects less convincing. Indeed, LSD

¹ Boccaletti, M., Guazzone, G., *Nature*, 252, 18 (1974).

produced apomorphine-like (contraversive) circling behaviour in only 40–50% of animals tested, and then at the very high drug levels of 1 and 1.5 mg kg⁻¹. In the turning mouse model of von Voigtlander and Moore², where 1 mg kg⁻¹ apomorphine induced a mean rate of turning of 5 min⁻¹, no satisfactory data for LSD could be obtained. In the dose range 0.025–0.2 mg kg⁻¹, LSD induced neither turning behaviour or postural asymmetries nor significantly modified apomorphine or amphetamine-induced circling, as may be predicted were it a potent dopamine agonist. Where rotation was induced following administration of 1.5 mg kg⁻¹ LSD the duration was of the order of 35–45 min; not 2 h as Pieri *et al.* suggest. We agree with them that rotation was prevented by previous treatment with haloperidol (0.5 mg kg⁻¹), and not after α -methyl-*p*-tyrosine (250 mg kg⁻¹).

In another experimental animal model, namely, audiogenic seizures in inbred strains of mice, dopamine agonists have been shown to diminish the severity of the seizure response^{3,4}. In our experiments, apomorphine was at least 10 times more potent than LSD in blocking the clonic phase of the seizure in 50% of animals.

The pharmacology of LSD is very confused, but has previously been associated with central 5-HT neurones^{5–7}. Pieri *et al.*, however, have claimed a direct and potent action of LSD on the dopaminergic receptor *in vivo*. Our data do not confirm LSD as being a potent dopamine agonist, although it seems to be capable of stimulating the dopamine receptor in very high doses.

PIERI ET AL. REPLY—The results reported¹ correspond to a well defined model, namely rats unilaterally lesioned in the medial forebrain bundle with 5,6-HT or 6-OHDA. These two types of lesion have been extensively investigated with biochemical^{2,3} and histofluorescence methods (H. P. Lorez, unpublished), and result in a marked and long-lasting depletion of dopamine (DA), possibly leading to the subsequent development of denervation supersensitivity, (1 mg kg⁻¹

apomorphine being able to induce more than 15 turns min⁻¹ for 30 min). Lesioned animals were challenged with apomorphine and only those responding with a clear circling (about 50–60%) were subsequently used for the study of the effect of other agents, including LSD (80% of responses). The data obtained with several hundreds of rats have been described in part previously⁴ and a more extensive paper is in the press⁵. The fact that Pycock and Anlezark⁶ seem to have used a different animal species and a different lesion, clearly yielding less denervation supersensitivity (1 mg kg⁻¹ apomorphine inducing a mean rate of turning of 5 min⁻¹), precludes any reasonable comparison.

Concerning the relative potencies of apomorphine and LSD as striatal DA receptor agonists, it seems from our data that LSD is slightly more potent than apomorphine. By no means, however, do we claim that this applies to completely different models such as that reported by Pycock and Anlezark⁶ (namely, audiogenic seizures in mice).

It should also be stressed that low doses of LSD elicit a significant slowing of DA turnover in rat striatum (0.2 mg kg⁻¹ intraperitoneally) and retina (0.5 mg kg⁻¹ intraperitoneally). In addition, the striatal adenylate cyclase is activated by concentrations of LSD as low as 10⁻⁸ M (ref. 7). Thus, there is also biochemical evidence for DA receptor stimulating properties of LSD.

We did not intend to suggest that the DA receptor stimulant effect of LSD observed in our experimental conditions should be the final answer to the confused pharmacology of the compound. The DA-like component of LSD action in the central nervous system is, in our opinion, additive and not alternative to the stimulant action of the compound on 5-HT receptors. In circling behaviour, however, DA receptor stimulation seems to be important, at least in our model⁵.

Mimetic talking by parrots

THE paper by Gregory and Hopkins¹ has prompted me to speculate on the question; What is the biological sig-

nificance (or survival value) of 'talking' by parrots? Of course, parrots do not actually talk, they only imitate speech. In fact, they imitate, not only speech, but many sorts of discernible sound patterns that are likely to be produced repeatedly in their environment. Indeed, the articulated sounds, I suggest, signify a kind of 'functional' mimicry, whereby an animal is camouflaged by becoming one more source of its natural environmental noise. Yet, the animal does not presumably utter the mimetic sound patterns at random times and spaces, but rather it may utter them as responses to specific outer signals. This behaviour implies the existence of integrated neuronal circuits; and as a dominant role of the visual system is known in birds², the pupil constriction observed, suggests that certain (learned) visual patterns may act as signals (stimuli) that trigger talking behaviour. Thus, pupil constriction may serve to obtain clearer, optimal images of such visual patterns. Guzmán-Flores (personal communication) has found that parrots fail to learn recurrent, tape-recorded utterances, in which the correlative significant visual stimuli are missing.

Hereditary persistence of foetal haemoglobin

ALTHOUGH the interpretation of Martinez and Colombo¹ may be correct, their conclusions are based on uncertain evidence and an alternative explanation that fits within the classical scheme is equally plausible. Their argument rests entirely on the statement that "foetal haemoglobin (HbF) levels show intrafamilial segregation in β^{thal} ". From this statement, they conclude that III₂ cannot simply be a β^{thal} heterozygote like I₂. Our experience shows that this is not invariably so: parents, offspring, and siblings who are β^{thal} heterozygotes may differ in level of HbF. Consequently, we believe that III₂ is only a β^{thal} heterozygote and that his slightly elevated HbF is the result of his particular expression of the condition. The inheritance pattern then follows normally. I₁, II₁, and III₁ all have a chromosome with S and hereditary persistence of foetal Hb (HPFH); II₁ also has β^{thal} ; III₁ and III₂ have a normal chromosome from II₂.

The presence of HbS and HPFH in the *cis* form has not been reported, but is entirely feasible from our knowledge of the genetics and arrangement of the complex of β , γ , and δ genes². A type of HPFH which has only about 5% HbF has been described³. We have recently examined a family in which, in contrast to other HPFH classes, β^A chains are produced in *cis* to HPFH (ref. 4) and have speculated that a type of HPFH with production of β^S chains in *cis* is possible. Martinez and Colombo may have detected this combination. They report, however, a heterogeneous intracellular distribution of HbF in I_1 and III_1 , whereas a homogeneous distribution is one of the criteria of HPFH. Consequently, it is more probable that I_1 and III_1 merely have sickle cell trait with somewhat elevated HbF.

In summary, we believe that Martinez and Colombo have misjudged the genetic aspects of several members of this family and have made unwarranted interpretations. In all probability, I_1 and III_1 have sickle cell trait, I_2 and III_2 have β^{thal} trait, and II_1 has S- β^0 -thal.

⁴ Huisman, T. H. J., Miller, A., and Schroeder, W. A., *Am. J. Human Genet.* (in the press).

DRS MARTINEZ AND COLOMBO REPLY—The argument put forward by Schroeder and Huisman¹ in their criticism to our paper² rests entirely on the sentence: "it is more probable that I_1 and III_1 merely have sickle cell trait with somewhat elevated HbF (foetal haemoglobin)", as confirmed by the last sentence of their letter. With this statement they want to imply that the elevation of HbF is determined by some non-genetical factor(s). This means that to interpret the elevated percentages of HbF in I_1 , III_1 and III_2 the following assumptions must be made. A subject and his grandmother, both showing HbS trait only, have exceptionally elevated percentages of HbF which are exactly the same (and by definition are not genetically determined); and a simple β^{thal} carrier is doubly exceptional because this subject not only shows HbF levels exceptionally high for this condition³, but also these levels do not show the intrafamilial segregation

reported by many authors (see, for example, refs 3 and 4). We consider that it must be very exceptional as only the opposite situation has been reported in the literature.

Being somewhat reluctant to postulate so many unwarranted hypotheses, we preferred to propose just one, that is, that in our family there was a segregation of a type of hereditary persistence of foetal haemoglobin (HPFH).

If we are in the presence of a type of HPFH the hypothesis that this HPFH is in *cis* to β^S (as mentioned and rejected also by Schroeder and Huisman) cannot be accepted for the following reasons: the ratio β^S/β^A was normal in I_1 and III_1 ; the gamete transmitted from II_1 to III_2 should be a recombinant between HPFH and β^S .

Thus the fact that the gene for this HPFH could not be in *cis* to β^S nor to β^A (see pedigree) enabled us to claim that we were in the presence of a "new type of HPFH".

It is evident then that the objection raised by Schroeder and Huisman concerning the intracellular distribution of HbF becomes completely irrelevant.

In summary, we believe that Schroeder and Huisman have misjudged the genotypes of all the members of this family showing elevated percentages of HbF. In fact trying to reject the most logical interpretation of our findings, they were forced to discard *tout-court* the possibility that this persistence of HbF was hereditary, thus creating for each member of the family the unwarranted, although unexpressed, number of necessary hypotheses.

Ultraviolet light and human cataract

WEITER and Finch¹ could find no difference in paramagnetic species between normal and cataractous human lenses but demonstrated that prolonged ultraviolet irradiation of normal human lens produced free radical species, which they presumed were derived from tryptophan. They suggest that the production of free radicals by ultraviolet light might be a mechanism for photoinduced lens damage.

The theory that the ultraviolet radiation of sunlight (or from other sources) can cause brown nuclear cataract has been the subject of prolonged discussion, but there are two major arguments against such a

theory²: (1) The proteins of the brown cataractous nucleus do not show a loss of tryptophan compared with the normal human lens³, whereas a substantial loss of tryptophan is found in the products of *in vitro* photo-oxidation of lens proteins³; and, (2) in brown nuclear cataract, only the lens nucleus is pigmented and it is difficult to see how ultraviolet light could act on proteins of the lens nucleus alone, rather than those of the cortex, which are very similar; especially as absorption of ultraviolet by the cornea and outer layers of the lens would ensure that little harmful radiation could reach the centre of the lens.

KEITH J. DILLEY

Nuffield Laboratory of Ophthalmology,
University of Oxford,
Walton Street, Oxford OX2 6AW, UK

¹ Weiter, J. J., and Finch, E. D., *Nature*, **254**, 536-537 (1975).

³ Buckingham, R. H., and Pirie, A., *Expt Eye Res.*, **14**, 297-299 (1972).

WEITER AND FINCH REPLY—The invariance of tryptophan content in normal and cataractous lenses as opposed to the loss of tryptophan in the *in vitro* photo-oxidation of lens proteins may result from the likelihood that the tryptophan in the lens proteins *in vivo* may absorb the radiation and transmit the energy to some other species (for example, lipids) to produce the radical, which may in turn cause damage to the lens. If this is so, the tryptophan would remain essentially unaffected. Steen¹ has shown that tryptophan in an ethylene glycol-water glass at 77 K absorbs ultraviolet light to produce the radical in the solvent, and tryptophan itself may not form the radical. The growth of radical, however, in both Steen's and our own (unpublished) experiments with lens material is not linear with respect to exposure time, thereby indicating the possibility of some degradation of tryptophan and its consequent unavailability for excitation. It is likely that this could be the result of a mechanistic detail rather than tryptophan degradation. Production of a radical through tryptophan excitation may involve several steps and this may diminish the efficiency of radical production.

The second point we would make is that Steen¹ has pointed out that the formation of free radicals by ultraviolet light on tryptophan in ethylene glycol-water glass is accompanied by significant coloration of the sample and this was attributed to trapped electrons. The trapping was most efficient in the presence of a substantial concentration of H^+ ions, which are known to scavenge electrons very well. If we assume that the cataract coloration results from trapped electrons, a differential cationic concentration between the cortex and the nucleus could explain this nuclear pigmentation through a colour

centre formation. Alternatively, the coloration may arise from the formation of stable lipid peroxides, although in this case, we do not know why the nucleus is favoured discriminately for the production of lipid peroxide radicals.

Reversibility and biological machines

GRAY¹, in discussing reversibility and biological machines, applied a formula derived by Brillouin², describing the energy required to determine the positional limits of a microscopic system, to the muscle cross bridge. A result of his analysis is that the cross bridge is too small to be controlled directly by any internal system which matches the tension to the external load, and that control must extend over greater distances; I doubt if anyone would contest this. Gray then, however, extends the concept of 'profitable controllability' from this restricted example to all machines of molecular dimensions which operate cyclically and argues that their mode of operation involves an irreversible, unidirectional step; if this is not so, then the efficiency of energy conversion must be very low indeed. This idea is identical to that of McClare³, who has argued that muscle contraction is an irreversible quantum-mechanical process whereby the free energy from ATP is converted to mechanical work. In fact, perfectly workable, self consistent models of muscular contraction can be made without any recourse to quantum mechanics, by general methods applicable to any energy conversion process⁴, but Gray claims to advance a definite proof that this is impossible and that biological molecular machinery cannot be considered as an energy converter in the classical thermodynamic sense.

This does not follow, however, from Gray's idea of 'profitable controllability' which only has meaning when the rate of working of a molecular machine is geared to the prevailing force-field (thermodynamic gradients or whatever) by some cybernetic process, to achieve a thermodynamically reversible operation. If this criterion does not apply the 'controllability' of the system is meaningless, or rather irrelevant. There is no evidence that molecular machines must be controlled in this way, and so Gray has only produced a proof for one highly restricted set of conditions. It is perhaps worth considering the case of such molecular machines

as ion pumps in the cell membrane, which can be driven backwards and which seem to function with high efficiency⁵. It is not possible to argue that there is no direct energy conversion occurring (as in a system involving mechanical work) because a substantial part of the work performed is that of moving a charge through an electric field gradient; that is, free energy from ATP is being used directly, by way of a conformational change, to achieve translation in a force-field. This must be taken to be a direct experimental disproof of Gray's thesis.

In summary, although the rate of energy conversion by a biological machine of molecular dimensions is subject to microscopic variation within the statistical limits imposed by the Second Law, there is no proof that size alone has any direct connection with the overall efficiency of the energy conversion process, or its potential reversibility.

A. E. HILL

Botany School,
University of Cambridge,
Cambridge CB2 3EA, UK

¹ Gray, B. F., *Nature*, 253, 436 (1975).

² Brillouin, L., *Science and Information Theory* (Academic, New York, 1962).

³ McClare, C. W. F., *Nature*, 240, 88 (1972).

⁴ Hill, T. L., *Prog. Biophys. molec. Biol.*, 28 (1975).

⁵ Garraban, P. J., and Glynn, I. M., *J. Physiol., Lond.*, 192, 217 (1967).

GRAY REPLIES—In the first few lines of his comment Hill¹ incorrectly paraphrases the contents of my letter, then identifies his version with a theory of McClare² (to which I did not even refer) which has been published for some time. He attributes to me claims which I do not make, for example, to advance a definite proof that "perfectly workable self-consistent models of muscular contraction cannot be made without recourse to quantum mechanics". Perfect workability, however, depends on how much or how little detail one is satisfied with in a theory. Hydrogen and oxygen will react explosively to form water

Matters arising

Matters Arising is meant as a vehicle for comment and discussion about papers that appear in *Nature*. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted. Neither contribution nor reply (if one is necessary) should be longer than 300 words and the briefest of replies, to the effect that a point is taken, should be considered.

and the statement $\Delta G < 0$ and its implications may be a 'perfectly workable self-consistent model' to some people who are interested only in distinguishing potential explosives from inert material. To the man interested in why the reaction is explosive, at one temperature and almost immeasurably slow at a temperature one degree lower, however, this 'perfectly workable' model is completely useless! He needs the macroscopic theory of chain reactions, and a third man with an even greater sense of curiosity needs quantum mechanics to understand the magnitudes of the reaction cross sections involved in this theory.

The first part of Hill's second paragraph reveals a misunderstanding of my main thesis, which is that very small (molecular) machines cannot be individually controlled if they are to work efficiently, not the reverse. He argues that there is no evidence that biological molecular machines are controlled "by gearing to some prevailing force field to achieve a thermodynamically reversible operation". He is here reiterating the view expressed by McClare³, and my letter shows this is necessarily true, from a consideration of quantum theory and the observed sizes and efficiencies of molecular machines. We seem to agree that the independent working units, such as a crossbridge or a pump site, cycle autonomously in normal conditions in their forward direction, that is, using ATP. Clearly they cannot be made to go in reverse without the intervention of control, by definition, thus giving a concomitant drop in efficiency for units of this size. Experimental results on the reversal of ion pumps³ do not conflict with this conclusion, since the reversal of the ion pump obtained in human red cells was achieved in highly abnormal conditions, not the normal environment of these cells and the energy expended in producing this abnormal environment must not be ignored in any discussion of efficiency and reversibility. Obviously any cyclic machine can be run backwards if one goes to sufficient lengths to push it, but there will be a drastic loss in efficiency except in the classical limit, where one can operate reversibly without energy cost. My brief statement about the reversal of muscle should be understood in this sense.

Hill's last statement does not seem to make sense, as the Second Law imposes no limits, statistical or otherwise, on the rate of energy conversion of any machines from molecular biological to macroscopic steam engines. It gives a criterion for distinguishing processes in which work can potentially be extracted from others in which it cannot.

reviews

RIBOSOMES are subcellular organelles that are found mainly in the cytoplasm. They are important because they are the site of protein biosynthesis, where the linear nucleotide sequence of messenger RNA is translated into the linear amino acid sequence of a particular protein. They may be regarded as multifunctional multisubunit enzymes and they are unusual because they contain RNA as a major component.

Ribosomes were first isolated and studied about 25 years ago. James Watson and Alfred Tissières began the study of the bacterial ribosome in the late 1950s and the complexity of the particle (at least 3 RNA species and at least 55 different protein species) began to emerge. For a time, during the period when the amino acid code was being solved, it was convenient to regard the ribosome as a black box. Around 1968 several developments took place that allowed a study of the black box itself. These developments included: the isolation of individual ribosomal proteins; the reassembly of functional subribosomal particles from their RNA and protein components; the preparation of antibodies to individual proteins and the invention of other techniques for analysing complicated protein mixtures; the emergence of nucleotide sequencing techniques; and the choice throughout the world of *Escherichia coli* ribosomes as the preferred system for study—this concentration on a single species has proved specially important—not least in promoting collaborative research.

This book arises from a meeting on ribosomes held in Cold Spring Harbor in September 1973 and fixes the view of the bacterial ribosome (particularly the *E. coli* ribosome) as it appeared at the meeting. The book has many admirable

Ribosomes

R. A. Cox

Ribosomes. By M. Nomura, A. Tissières and P. Lengyel. Pp. x+930. (Cold Spring Harbor Laboratory Press: Cold Spring Harbor, New York, 1974.) \$32.00.

features. The first part comprises a series of general reviews. The editors have carefully chosen the contributors from those invited to the meeting, and a few who were themselves the pioneers responsible for some of the most recent advances were asked to provide more general surveys of topics such as RNA-protein interactions in the ribosome, the protein topography of ribosomal subunits, and the reconstitution of ribosomes, as well as reviews of physical properties of ribosomes, and of the isolation and properties of RNA and proteins. The process of translation, ribosome genetics and ribosome biosynthesis are also reviewed. The reviewers generally produced more than a factual survey and have emphasised where possible the relationship between structure and function. By no means all of the progress achieved in ribosome research has a chemical basis but a major impression remains that a chemical approach has proved to be fruitful for probing ribosome structure and eroding the 'black box' concept. For example, it can now be said "that the fidelity with which messenger RNA can be translated depends critically on the amino acid residues at positions 42 and

87 of protein S12". Bifunctional cross-linking agents have proved useful in identifying those proteins that are neighbours in the ribosome, and affinity labelling methods have been used increasingly to identify functionally active groups.

The second part of the book is made up of a series of carefully selected "Specific Reviews" of topics such as electron microscopy, affinity labelling techniques, immunochemical analysis, fluorescence studies, ribosome genetics, "magic spot", RNA synthesis *in vivo* and *in vitro* and particular aspects of ribosome function. There are three specialist reports on antibiotics and the ribosome but no general review of this topic although widespread use is made of these substances as probes of ribosome structure.

The glory belongs to the *E. coli* ribosome but about a fifth of the book is devoted to ribosomes of eukaryotes. There is one chapter and one specific report devoted to eukaryotic ribosome structure. This emphasis is, however, a fair reflection of the field as a whole.

The book comprises 930 pages and a comprehensive index. It provides a very clear picture of the *E. coli* ribosome as it was seen in late 1973 with the proteins preeminent and the RNA moiety in the shadows; and it also reveals and documents the remarkable progress made over a five-year period. It is a monumental effort that does justice to the subject—indeed, it is the most ambitious publication in the field so far—and the standard of precision and clarity it achieves in giving shape to so many diverse facts is very high. This book has much to offer those who are interested in nucleoproteins and it is compelling reading for those who are actively interested in ribosomes.

THE concept of aromaticity in organic molecules, which has done so much to inspire experimental work in both mechanistic and preparative areas, is still the subject of much debate and controversy. The present volume sets out to present the varied aspects of aromaticity in a critical and concise manner and the result is a very readable account of the present status of the subject. What is lost in detail in the text is compensated for by an extensive list of references so that the reader will have no difficulty in

Aromaticity

A. W. Johnson

Facts and Theories of Aromaticity. By David Lewis and David Peters. Pp. viii+109. (Macmillan: London and Basingstoke, April 1975.) £10.00.

following up any particular aspect. After a brief historical introduction, chapters are given on experimental evidence,

theoretical ideas and simple examples of aromaticity and a variety of non-benzenoid structures: for example, quinoids, pyrones and porphyrins are also considered. Finally, ideas on homoaromaticity and antiaromaticity are summarised and some general conclusions are advanced. It is an interesting text on a topic of interest to all organic chemists and it is well written and produced in an attractive format, as indeed would be expected for about 10 pence a page.

Books for Autumn 1975

Fish Communities in Tropical Freshwaters

R H Lowe-McConnell

By reference to ecological studies in freshwater fishes, this book illustrates how tropical fish communities differ from those in temperate waters. The book makes available to the general ecologist the results of recent research into the ecology of the fish.

Although the book is intended primarily for college and university students it will be of interest to the general reader concerned with ecological concepts, zoogeography or fish biology.

Guidebook to Stereochemistry

F D Gunstone

This guidebook provides a foundation for the understanding of stereochemistry - a subject which is of fundamental importance in all sciences studied at the molecular level. As most molecules exist in three dimensional form, molecular shape must be understood in order to rationalise and predict chemical and biological behaviour. There are chapters dealing with *cis-trans* isomerism, enantiomerism, conformation, and dynamic stereochemistry.

£2.95 net

Forthcoming:

Heterocyclic Chemistry

D W Young

An introduction to the chemistry of heterocyclic compounds for students of chemistry, pharmacy and biochemistry, who possess a basic knowledge of biochemistry. The reactions of heterocyclic compounds are compared with those of their simple organic-functional group analogues by noting how ring and heteroatoms interact to produce the unique properties exhibited by heterocyclic compounds.

The chemical effects of aliphatic heterocyclic compounds are discussed, and consideration is given to aromaticity and tautomerism, leading to a discussion of hetero-aromatic compounds in general.

Longman

Quantum optics

Introduction to Quantum Optics. (Documents on Modern Physics.) By H. M. Nussenzveig. Pp. xiv + 246. (Gordon and Breach: London, New York and Paris, December 1974.) DM 59; \$24.40.

Optical Resonance and Two-Level Atoms. (Interscience Monographs and Texts in Physics and Astronomy, vol. 28.) By L. Allen and J. H. Eberly. (Wiley Interscience: New York and London, March 1975.) £10.80.

ALTHOUGH the range of topics discussed in these books is not identical there is, nevertheless, some relationship between them. One obvious link is that Professors Nussenzveig and Eberly are both in the same department of the University of Rochester. Furthermore, the books are of comparable length and depth, and are clearly intended for the same type of audience. And both include chapters on superradiance, a topic that has so far received little text book coverage.

In *Introduction to Quantum Optics*, the foundations of the subject are treated in a fairly standard way. The bulk of the book is based on a series of lectures presented by the author at the Latin American School of Physics in La Plata in 1970, and is devoted to the classical and quantum theories of optical coherence and the semiclassical and quantum theories of the laser. A chapter has since been added on coherent interactions, in which superradiance, photon echoes and self-induced transparency are described from a semiclassical viewpoint. The book closes with a rather disjointed 30 page appendix on recent developments (much of which is devoted to the quantum theory of superradiance), which certainly serves to emphasise the unfinished nature of quantum optics research. The style throughout is very readable and there are adequate references at the end of each chapter.

The book is by no means unique in its coverage, apart from perhaps the welcome inclusion of superradiance. In his introduction, Professor Nussenzveig states that the book is "aimed at theoretical physicists and graduate students . . . as an introduction to a new subject with which no previous familiarity is assumed". One happy consequence is that the level of presentation is not so high that the experimentalist will immediately be daunted. In this, perhaps, lies the book's particular merit.

Optical Resonance and Two-Level Atoms is more original in conception, bringing together material that has until now been widely scattered in other books or reported only in research journals. Indeed, it forms an excellent sequel to *Introduction to Quantum Optics*, being devoted entirely to the resonance phenomena treated in the last chapters

of Professor Nussenzveig's book. Both authors have published extensively in this field although the stated intention of the book is not to emphasise recent research but rather to reveal the general principles involved. The first chapter deals with the classical theory of absorption from an unconventional point of view which allows the authors to introduce the idea of pulse "area". An examination of the validity of the two-level assumption and a useful discussion of the various other approximations commonly used leads on to an extended treatment of Bloch vector dynamics and self-induced transparency, which forms the central section of the book. Experimental results are compared with the theoretical predictions, the possible confusion of self-induced transparency with incoherent saturation effects being carefully explained. A chapter on single-atom spontaneous emission using quantised field theory lays the groundwork for the discussion of cooperative phenomena, superradiant decay and photon echoes which forms the second part of the book. The style of writing is clear and informal and the emphasis throughout is always on the physics of the processes taking place. There are numerous helpful illustrations and adequate lists of references.

Both *Introduction to Quantum Optics* and *Optical Resonance and Two-Level Atoms* represent welcome additions to the literature on quantum optics. The latter will prove particularly valuable because of its unusual coverage, although both can be warmly recommended.

G. H. C. New

Pictish horse and foot soldiers form a battle scene on the back of a Pictish sandstone cross slab, Aberlemno churchyard, Aberlemno, Angus, Scotland. Taken from *Scotland: An Archeological Guide* by Euan W. Mackie. Pp. x + 298. (Faber and Faber: London, June 1975.) Cloth £5.50; paper £2.95.

Seismic Waves. By E. F. Savarenskii. Translated from Russian. Pp. vi+281. (Israel Program for Scientific Translations: Jerusalem; Wiley: Chichester; May 1975.) £13.95.

THIS book, excellently translated, caters mainly for the physicist who wants to study elastodynamics and that part of data-handling needed with seismic data. There are three chapters: the first, on oscillations, deals mainly with Fourier analysis and operations in the frequency domain; the second, on waves, derives the basic equations of elastic wave motion and goes on to obtain radiation fields for point sources in an unbounded medium; the third describes the propagation of plane seismic waves in a half-space or a layer.

The book is written at a fairly elementary level, and mathematical demonstrations are sketchy. It omits, for instance, mention of the splitting of degenerate eigenfrequencies of the Earth, or of matrix methods for layered media. The reader will not find such recent topics as earthquake prediction, lunar seismology or deep seismic sounding. Within its scope, Savarenskii's book is clear and practical; it has obviously grown out of the experience of an expert seismologist. **E. R. Lapwood**

Bee Research Association, 1949-1974: A History of the First 25 Years. Pp. 199. (Bee Research Association: Gerrards Cross, 1974.) np.

LAST year was the 25th anniversary of the founding of the Bee Research Association and to help commemorate the first quarter of a century a history of the association, to which many of its prominent members have contributed, has now been published.

The history traces the foundation of the Bee Research Association as an offshoot of the research committee of the British Beekeepers' Association, its growth in size and importance to an international organisation and its acquisition of a permanent headquarters at Hill House in Chalfont St Peter. During this process it took over publication of the well established journal *Bee World*, introduced *Apicultural Abstracts*, first as an integral part of *Bee World* in 1950 and then as a separate quarterly journal in 1962, and launched *Journal of Apicultural Research* in 1961 in response to a strongly felt need for a journal devoted to experimental work relating to pollination and beekeeping.

Bee research workers and advisory officers readily acknowledge the value to their work of these three journals and the many other facilities the association provides, including its library of re-

prints, books and translations, all of which are discussed at length in this book. With the recent increase in beekeeping and in the use of bees for pollination, especially in developing countries, the services of the association are in greater demand than ever before. It is vital that they should continue to grow.

Books brief

Atomic Physics.. (The Manchester Physics Series.) By J. C. Willmott. Pp. xiv+357. (Wiley: London and New York, April 1975.) £8.50 cloth; £4.25 paper.

THIS textbook is intended for the second year of the honours physics course at an English University, specifically, Manchester, whose reputation in atomic and molecular physics is high. The book contains the necessary quantum mechanics, and inevitably, material that might be taught in the first year, and material that would in the opinion of some belong in the final year. But it stops short of Lamb shift and hyperfine structure. The author is primarily a nuclear physicist, and it is to some extent a reflection on atomic physicists that the subject is not particularly well served by undergraduate texts; for this reason, the book will fulfil a useful role. It is a competent book, although not everyone will find it inspiring. There are sets of problems in each chapter, and it is well produced and indexed.

J. B. Hasted

Registry of Mass Spectral Data; volumes 1-4. Edited by E. Stenhagen, S. Abrahamsson and F. W. McLafferty. Pp. xvii+3,358 (Wiley, New York, 1974.) £250.00.

WHEN it was first developed and became commercially available in the early 1960s, mass spectrometry was hailed as the panacea that would take the pain out of structure elucidation. No longer would organic chemists have to slave for months, if not years, degrading and analysing new compounds; instead a mass spectrum would tell all, and even a milligram of material would be sufficient. But this early euphoria was not wholly justified, and since then in the years of appraisal that followed, the limitations and the complications of mass spectrometry have become apparent. Although the expert practitioner, backed up by expensive and elaborate computing facilities, is able to

combine mass spectral fragments and deduce the structure of his unknown, the average organic chemist can deploy neither expertise nor facilities on this scale. Instead, he merely compares the spectrum of his unknown with those of known compounds and attempts to spot significant similarities.

This is where the *Registry of Mass Spectral Data* fits in. It is an immense and invaluable collection of reproductions of 18,806 authentic mass spectra. The spectra themselves are easy to locate, being arranged in order of increasing molecular weight (to the nearest whole mass unit); there is also an excellent index. Although expensive, the cost is, in fact, less than two pence a spectrum, and when the price of even the most modest mass spectrometer is considered, the additional expense in purchasing this unique compendium of spectra as an accessory is easily justified. I strongly recommend the *Registry of Mass Spectral Data* as a must for every laboratory in which mass spectrometry goes on; it cannot afford to be without one.

E. J. Thomas

Biological Transport. Second Edition. By Halvor N. Christensen. Pp. xvi+514. (Benjamin: Reading, Massachusetts and London, April 1975.) \$19.50.

NOWADAYS, the term 'Biological Transport' concerns the nature of, and mechanisms underlying, the transport of substances between different phases separated by membranes (for example, plasma and mitochondrial) or by epithelial structures (for example, intestine, placenta, renal tubule).

This second edition of H. N. Christensen's excellent book is really a complete new work and the author is to be congratulated on attempting to embrace within one volume all aspects of epithelial transport and membrane structure and function, including kinetic, thermodynamic and genetic aspects of real and artificial systems. He has largely succeeded in surmounting the disciplinary prejudices that seem to have caused an exceptional degree of fragmentation in the subject, and the book will accordingly be useful to workers studying membranes and epithelia.

The account of the ATPases seems somewhat old fashioned; vitamin B₁₂ is not absorbed in the duodenum; the electron micrograph of the erythrocyte is an antique; and after page 367 the contents page and the text become out of phase. But there is much in this book for those interested in any aspect of biological transport, and that must include biochemists, morphologists, physiologists and molecular biologists.

Dennis S. Parsons

obituary

Gordon Mayer Tomkins of the University of California, San Francisco, one of America's most distinguished biochemists and a pioneer research scientist in the field of hormone activity, died in New York City, July 22, 1975. He was 49 years old. He had been ill since undergoing brain surgery in late May.

To his colleagues in scientific institutions all over the world Dr Tomkins was an extraordinary individual. He was a physician, a highly creative scientist, a teacher of unparalleled enthusiasm and an accomplished musician who played both classics and jazz with distinction.

Dr Tomkins was born in Chicago and received an A.B. degree in Philosophy from UCLA, an M.D. degree from Harvard Medical School and a Ph.D. degree from the University of California, Berkeley. He spent 16 years at the NIH, Bethesda, Maryland, and left there in 1969 as Chief of the Laboratory of Molecular Biology, National Institute of Arthritis, Metabolism, and Digestive Diseases, to join the University of California, San Francisco, as Professor of Biochemistry.

He served on numerous editorial boards for scientific journals and

periodicals and was the recipient of many honours, including the Mider Lectureship (NIH, 1969); the Jesup Lectureship (Columbia, 1971); the Harvey Society Lectureship (Rockefeller, 1972); the Prather Lectureship (Harvard, 1972); and the Baker Lecture (Cornell, 1975).

His scientific contributions encompass broad aspects of biological chemistry and molecular biology. His first publications described the regulation of cholesterol biosynthesis by diet. From this early involvement with sterols developed his intense interest in steroid hormones and their molecular mechanisms of action. He described the now important enzymatic reductions and hydroxylations of steroids and soon after introduced the concept of and provided evidence for a low molecular weight compound, such as a steroid hormone, specifically changing the conformation of a protein molecule. This concept, subsequently termed allostery by others, is an important one not only in endocrinology but for most of molecular biology and biochemistry.

He was responsible for developing a system in which the mechanism of steroid action and the regulation of gene expression can be studied in continuously cultured mammalian cells, a system which is widely used in research laboratories today and which in recent years he extended to the selection and isolation of mutant cell clones with altered responses to steroid hormones and cyclic nucleotides. This approach is providing insights to many of the fundamental problems in endocrinology and is playing a significant role in the further acquisition of knowledge in fields of genetics, cellular and developmental biology, and cancer.

Equally important were his theoretical contributions to a variety of biological and medical fields. He introduced the idea that the regulation of the levels of specific proteins might occur at steps subsequent to the formation of their messenger RNA molecules. From a consideration of the problem of the transformation of a normal cell into a malignant or cancerous one with uncontrolled growth, he developed a unifying theory of growth regulation termed 'pleiotypy' by which a normal cell, unlike its malignant counterpart, coordinates a diverse set of intracellular reactions to arrest its growth in response to extracellular

conditions. In his final theoretical contribution, he described a plausible mechanism to account for the evolution of hormonal regulation, that is characteristic of multicellular organisms, from simple unicellular organisms.

His impact on medical research has been generated not only by his training and education of numerous esteemed scientists and physicians throughout the world but also by the unusual excitement about science that he created among colleagues and acquaintances.

To those who knew him scientifically, his death is the loss of exciting ideas; to those who knew him musically, the loss of distinguished talent; to those who knew him personally, the loss of intellectual brilliance, extraordinary wit, great warmth and charm. To those who were fortunate enough to experience all of these various gifts, his death is the end of an era.

Reiji Okazaki, the Japanese molecular biologist, died on August 1 at the age of 44.

Okazaki arrived at the forefront of molecular biology in 1966 with his discovery that the synthesis of new DNA strands during the process of DNA duplication seems to occur in rather short sections (now known to everyone as 'Okazaki pieces') that only later are joined together to make the long uninterrupted strands of the finished product. This finding explained how two new strands of opposite polarity could be synthesised at a single locus travelling in one direction along the parental double helix, and it therefore reconciled the properties of DNA polymerase with the large-scale structure of replicating DNA. Since then he had worked indefatigably to determine what is the direction of synthesis of the short pieces of DNA, how they are started and how finally they are joined together. These experiments involved a very high level of technical sophistication and were followed with great interest by all workers in the field. Okazaki was a schoolboy in Hiroshima when the bomb was dropped and this may have been the cause of his death, from leukaemia—a young man still at the height of his powers. At the time of his death he was professor of molecular biology at Nagoya University in Japan.

Don't rush them to predict earthquakes

MORE people died in Turkey last Saturday as a result of an earthquake than have ever died in the United States from earthquakes. And yet earthquakes in the United States attract an enormous global attention. One reason is simply human curiosity that a technological leader can be laid low by acts of God; for much the same reason are medical bulletins of heads of state read with fascination. A more subtle reason is the extraordinary way in which the lessons of every new major earthquake have been very rapidly learnt, although no doubt one could argue that the biggest lesson of all—don't live in regions prone to earthquakes—has yet to be assimilated.

The United States represents, in very crude terms, much less than a thousandth of the world's earthquake fatality potential—first, because a relatively small proportion of the world's active fault system is located in the United States; second, and more important, because awareness of the earthquake hazard is higher and thus elementary defensive measures are more widely practised, particularly in construction. Few people die from the shaking itself; it is the falling of buildings, the collapse of dams, the starting of fires and so on which claims life.

There is a worldwide interest in the earthquake prediction programme in the United States (completely over-shadowing the arguably more interesting and important programmes in the Soviet Union and China). This interest is bound to grow with the publication of *Earthquake Prediction and Public Policy*, an extensive document from the Panel on the Public Policy Implications of Earthquake Prediction under the chairmanship of Professor Ralph Turner, a sociologist from the University of California, Los Angeles. The layers of bureaucracy in Washington are so thick that initials must suffice to describe the report's parentage and destination: it was prepared by the PPPIEP of the ACEP, CSS of the NAS/NRC for the FDAA of DoHUD.

Predicting the reaction of the public to an earthquake warning seems to be every bit as difficult as predicting the earthquake itself, and this, no doubt, contributes in great measure to the unmemorability of much of the report. No stone could be said to have been left unturned, even down to expressing concern that tourists be alerted and jewellers empty their shops. The consequences of a prediction could be enormous; evacuations, unemployment, political in-fighting, demands for more money for emergency services, nuclear reactor shutdowns, draining of dams, attempts to withdraw insurance cover, failure to keep up mortgage payments, political attacks on scientists, local/state/federal squabbles, profiteering in property sales, demolition of buildings. The consequence of error is appropriately large. Small wonder then that it has already been said by Garrett Hardin that prediction could be more devastating than the event itself. The committee's first

recommendation is that "The highest priority . . . should be . . . saving lives, with secondary attention to minimising social and economic disruption and property loss, *provided the costs of specific measures are within the limits that society is willing to accept*" (our italics). Quite apart from the vagueness introduced by the second half of the recommendation, it is entirely possible that the social and economic disruption and property loss from the prediction will greatly exceed that from the earthquake, and might counterbalance the benefit from lives saved.

The panel did not find this very acceptable; it was passed off as "a popular theme currently espoused among some scientists and science popularisers". Another idea that it didn't like was that scientists might desist from making public pronouncements, at least for a few years. "Earthquake prediction is a fact at the present time . . . attempts to suppress information concerning premonitory signs would certainly fail—as they should". Now this is half-truth. Many scientists with the best will in the world towards prediction are looking very carefully at the limited evidence available and still wondering not only how universally applicable predictive phenomena may turn out to be but also whether the quality of the data that will be accessible without an enormous investment of cash will be sufficient to give unambiguous warning in more than a very few zones. And which zones are to be favoured? There are, in California, as many major earthquakes off the San Andreas Fault as on it; no-one foresaw the San Fernando Valley as a danger zone in 1971. Earthquake prediction is a fact in much the same way that travel to the moon is a fact.

Further, it is only half-true to say, as does the report, that "there is no way to monopolise prediction capability" (and thus to prevent predictions being made). The tools required for prediction include access to a whole range of data libraries, and were the government to impose a moratorium on public announcements while seismologists were given time to conduct more thorough research, it is not at all clear that any independent agency would either wish or be able to jump the gun. There might be a general welcome in all communities, scientific, governmental, legal, insurance, constructional for a long pause before prediction was permitted. The spectacle that this report portrays is rather the opposite; of a well meaning panel riding a small band of experts as fast as possible towards a confrontation with nature.

On two counts, then, this report gives cause for concern: that scientists may be rushed, and that the case against making a major response to a prediction may not be adequately examined. And Turkey's misfortunes underline yet again how little even elementary information on earthquake proofing crosses national frontiers. □

Eden with oil wells

The stereotyped image of the oil-rich countries of the Arab Peninsula is that of an artificial, fragile, air-conditioned Eden made possible by the purchase of Western comforts, technology and scientific background. The picture holds an implied threat of collapse by the time oil reserves become depleted which, by most reckonings, should happen sometime during the next century, perhaps in the first half of it. That image is, however, only partly true. Large investments are being made in an attempt to achieve what should amount to a leap from the Middle Ages to the atomic era. On the Arab Peninsula, schools have blossomed and primary education has, in most cases, become compulsory. Technical training facilities have been established, medical schools are about to produce their first graduates and, in Saudi Arabia, one of the world's most modern specialist hospitals has opened its doors. Alexander Dorozynski reports on science and technology on the Arab Peninsula, where the avowed aim is to achieve scientific and technical self-reliance as rapidly as possible, and which, if the present effort is maintained, may well become the site of a unique achievement.

ALTHOUGH per capita income in several countries of the Arab Peninsula is among the highest in the world, income as a product of labour is among the lowest. Wealth has not had time to filter down to the majority of the population, and rich countries such as Saudi Arabia and Kuwait are still developing nations. But the means for rapid scientific and technological progress essential to development are available, and it seems that Arab leaders have understood the need to provide for future generations.

Thus, not only is there an effort to transfer Western technology, but to revive a scientific tradition that has largely been dormant since the days when the Arab empire extended from Spain to Samarkand, when cultured Arab envoys expressed surprise at the illiteracy of Charlemagne's court, and Arab scientists helped pave the way for the European Renaissance.

In Saudi Arabia, for example, illiteracy was widespread only 20 years ago, and the only centre of higher learning was the Islamic Studies Faculty, founded in Mecca in 1947. But since the University of Riyadh was founded in 1957 with a teaching staff of nine, the situation has changed rapidly. The College of Petroleum and Minerals (CPM) was set up with the help of the Arabian American Oil Company in 1963, and the Abd al-Aziz University was started in 1967 as a private institution sponsored by a group of business and political leaders.

Now Riyadh University has an enrolment of 6,000 students (about as much as the 100-year-old American University in Beirut) in eight faculties: arts, education, sciences, business, pharmacy, agriculture, engineering and medicine. The Faculty of Medicine, is provided with professors, advisers and examiners by the University of London, and it will be the first faculty to move, in three or four years' time, to the \$500 million campus now being erected on the outskirts of the city. (In fact there will be two campuses, one for men, one for women.)

The Faculty of Sciences publishes a staff bulletin, whose contents reveal the wide range of interest and varying degrees of sophistication of research projects. A single issue, for example, contains a fairly simple and straightforward description of the morphology of the grasshopper and an analysis of climatic elements in the kingdom (with emphasis on potential agricultural developments), but also reports on subjects such as the electron spin resonance of several compounds. Professor A. A. Al-Khayal, Dean of the Faculty of Sciences, already voices a complaint familiar in academic circles, although unexpected in Saudi Arabia: lack of funds for facilities and

laboratory equipment.

The CPM, moving to an elegant, futuristic looking campus and chaired by Sheikh Ahmed Zaki Yamani, Minister of Petroleum and Minerals, teaches sciences, engineering science and applied engineering to some 1,000 students. High standards of admission are maintained by professors who, for the most part, come from American universities. The Abd al-Aziz University (arts, sciences, business and administration) has been integrated into the kingdom's educational system, and now has nearly 3,000 students.

These numbers alone, for a country of some 6 million people suddenly emerging into the modern world, represent an achievement. Another is the fact that women, traditionally kept outside the mainstream of life, now have access to primary and higher education. (This is attributed to the late King Faisal himself, and the influence of his wife, Iffat.) More than 200,000 girls, as well as half a million boys, attend school, and the numbers are constantly growing. Riyadh and Abd al-Aziz Universities have special teaching facilities for women. There is a shortage of women professors, and in many cases female students in separate quarters follow courses on closed-circuit television, and ask questions by telephone. Education at all levels (as well as medical services) is underwritten by the government.

Foreign observers familiar with Saudi institutions of learning generally agree that the level of standards is good and improving rapidly, particularly in professional education. But a straightforward comparison with Western institutions, which benefit from centuries of academic background and where religious and traditional values play a less important role, is difficult. Nevertheless, the admission of Saudi graduates as doctoral candidates at such institutions as MIT and Caltech is indicative of the standard that can be achieved.

An interesting (and controversial) initiative in Saudi Arabia has been the creation of the King Faisal Medical City and Specialist Hospital, which was inaugurated in April (before the graduation of the country's first crop of medical doctors). Conceived by King Faisal himself, the project was carried out under the leadership of Dr Rifat Alsayed Ali, personal physician to King Faisal and the royal family, who has coordinated the activities of dozens of foreign companies which have contributed to the building and equipping what is to become one of the world's most modern in-patient and out-patient specialist hospitals, offering facilities and skills seldom available under a single roof. The 250-bed hospital will be operated by an inter-

national staff of 750, part of which has already been contracted for. Future capacity will be 500 beds, with a staff of 1,200. Later this year, a clinical research department will be opened.

The idea, says Dr Ali, is not only to provide on-the-spot diagnostic and treatment facilities that many wealthy Arabs may seek in Boston, London or Paris, but to seek rapid medical progress in the region with the help of top foreign experts for whom the best possible working and living conditions are being provided.

The hospital has started operating on a limited scale, and on a paying basis. "Otherwise", says Dr Ali, "everyone will want to come here rather than to another hospital. But if any patient requires facilities and specialist treatment available only here, he will be admitted as a free patient if he cannot pay."

Another ambitious project in the kingdom is the development of agricultural research, considered as essential to self-reliance; the recently constructed laboratory of the Ministry of Agriculture near Riyadh is one of the most complete in the world in its design and equipment. It has yet to be fully staffed.

In Kuwait, where the development of a welfare state was started in 1951 by Sheik Abdallah as-Sabah and continued by his son and successor, Sheik Sabah as-Salim as-Sabah, schools have proliferated to provide for now compulsory primary education, and there is a splendid university (with a campus for women) which has research facilities with the latest equipment.

The progressive integration of women in a man's world is, here, more evident than in Saudi Arabia, where even secretaries are male. In Kuwait, women secretaries wearing modern dress are a common sight, and female researchers go unnoticed.

The Kuwait Institute for Science Research (KISR) has been operating for five years, and its prime purpose, in the words of its director, Mohammad Al Shamali, "is to build up a tradition for research. It is the first step, and perhaps the most difficult one to take."

While pursuing this goal, the KISR concentrates on research projects particularly suitable and useful to the country. Dr Al Shamali has long been interested by the potential use of indigenous desert plants, and a multidisciplinary research team led by Ibrahim Hamdan, an American-educated food scientist of Palestinian origin, is now trying to determine their nutritive value and their potential toxicity.

There are several hundred varieties of desert plant, perennial, annual and bushes, and little is known about them except that a little care, and a little more water, can greatly increase their

ONE of the most important catalysts to development in the Middle East is the Kuwait Fund for Arab Economic Development, created in 1961 as a government agency but granted complete independence in its finances, organisation, and policies. As Abdlatif Y. Al-Hamad, its Director General, likes to point out, one of its first principles is neutrality with regards to political and social systems adopted in the Arab countries. This neutrality seems to be more than simply token, as the fund has supported projects in countries with widely different political systems, such as Southern and Northern Yemen, Syria, Tunisia, Egypt and Mauritania.

Until last year, the Kuwait Fund functioned essentially as a regional development bank, providing assistance chiefly in the form of loans on concessionary terms, with interest rates around 3 or 4%, maturity about 20 years, and grace periods generally corresponding to the time needed for the completion of a project. (Some grants were also given, notably for technical assistance and the financing of technical or economic studies.)

In July 1974, the fund took a new turn when the National Assembly extended its operations to the rest of the developing world, and increased the declared capital from KD 200 million to KD 1,000 million, that is, more than \$3,000 million. Since then the fund has undertaken to support a number of development projects in Africa (livestock and sugar industry development in Uganda, river basin development in Senegal, tea plantations in Rwanda, textile spinning and weaving in Tanzania, construction of two harbours and a railway in Gabon)

Other projects are being studied,

and the fund's director general has visited Asia, where several projects are expected to receive financial support (a urea plant in Sri Lanka, sugar factories and land reclamation in Afganistan, irrigation in Bangladesh, land rehabilitation in Malaysia).

In 1971 the Kuwait Fund was followed by the Arab Fund for Economic and Social Development, with headquarters also in Kuwait. The Arab Fund's charter restricts its activities to Arab countries, where joint developments are planned in such fields as highway transportation, telecommunication and agriculture. Finding that there is a shortage of well-prepared national or regional projects, the Arab Fund has undertaken its own studies to help the development of a country in its regional context.

There doesn't appear to be an 'OPEC strategy' concerning aid to developing countries, but many OPEC members have reacted to the often-voiced charge that increased oil prices have crippled the development of poorer countries. Thus India has benefited from credit terms to obtain oil from Iran, Iraq and the United Arab Emirates, and for the poorer African countries, Arab oil producers have created a \$200 million fund to offset higher oil prices. Joint ventures have also been undertaken between rich and poor countries, for instance, between Kuwait and Mauritania to develop iron mines.

As there is little coordination between the various forms of aid financed by the OPEC, total figures are difficult to come by, but one estimate is that last year, more than \$5,000 million was committed to developing countries, either directly or through international agencies.

growth rate. Some of them have a good protein content, and, in a region where most of the fodder for cattle is now imported at considerable cost, they represent a potentially important natural resource.

A first step in the research project has been the identification of the principal varieties, some of which also exist in similar semi-arid regions of Australia, South and North America, but about which data is scattered or incomplete. This is now being followed by a determination of their nutritive value: a more sophisticated analysis of their carbohydrate, protein and crude fibre content. According to Ibrahim Hamdan, one perennial plant, atriplex, has been found to have a protein content of 16%, as high as that of alfalfa.

Many of the plants have been grown on the grounds or in greenhouses of

the KISR, and it has been shown that some of them may be suitable as a local substitute for more classical grazing plants that are costly to grow in the semi-arid tropics. Plants from regions with similar soil and climatic conditions have been included in the study, and attempts are being made to create a symbiosis between some desert bushes, annuals, and perennial plants (for instance, a deep-rooted shady bush, a climate-resistant perennial, and a succulent annual).

Recently, the cattle-feeding experiments were started on a desert plot of 20 square kilometres, acquired by the institute, and ways are being sought to complement this roughage with locally available additives, such as single-cell 'petroleum proteins' or microscopical algae (which are also experimentally grown at the KISR).

Toxicity studies have allowed the project to branch out into the study of the potential medicinal properties of some of the plants. Ali Anani, a chemist, has identified a number of alkaloids and other substances that are being studied in the particular context of traditional Kuwait medicine, which itself is probably an offshoot of ancient Arabic medicine, still practised by healers (*attarin*) who coexist in Kuwait with the free, Western-style medical services provided by the state. The *attarin* use herbal medicines, but jealously guard their secrets, sometimes mixing a number of substances in their preparations, apparently to camouflage the active ingredients. Some of the plants have already been shown to possess antibacterial activity. Soil bacteria and fungi have been included in the study, as well as hormone-like promoters of plant growth and soil enzymes that could be used to improve fibre digestibility.

Dr Mohammad El Shamali and Dr Hamdan believe this research may well turn out to be of significant importance in the development of agriculture, but also that it is a good way to train researchers of varied disciplines and nationalities to work together as a team.

It would be meaningless, again, to compare research undertaken in Kuwait with that of an MIT, Rockefeller or Pasteur Institute. But the effort is obvious, and the results, considering the lack of research background and tradition, encouraging indeed.

The pattern is repeated elsewhere on the peninsula. In the small state of Bahrain (where oil was found in the early 1930s) there are more than 100 schools for a population of 220,000, and several vocational training centres. In tiny Qatar, there is a technical school, a school of commerce, a teacher's college, and a total of about 90 schools; last year, the ratio of teachers to the population was about 1 to 1,000.

At the same time, the 'technological transfer' continues, with an increasing amount of goods being produced on the spot (albeit with the help of foreign technicians) rather than imported. Thus, while a few years ago the story was that a desert prince would discard his Cadillac when the ashtray was full or the tank empty, now there is a plant in Saudi Arabia where cars are overhauled and rebuilt, and arrangements are under way to set up assembly plants. In Riyadh, production of pharmaceuticals is expected to start this year; the General Petroleum and Mineral Organisation (Petromin), a public corporation owned by the state, runs a steel rolling mill on the Red Sea coast south of Jiddah. Local

THE government of Saudi Arabia is planning to spend \$12,000 million of its oil wealth in an effort to turn the country's desert green.

The desert lies 180 miles east of Riyadh and is the centre of a massive desert reclamation programme, part of a \$143.5 thousand million five-year development plan.

Altogether, the Saudi Arabian government plans to turn 4.18 million hectares of sand into farmland, which according to the Under Secretary of Agriculture, Mr Taher Efeid, will take at least half a century to accomplish.

At present, only 1.4 million acres of farmland are cultivated in the desert monarchy. This earns more than \$25,000 million in revenues annually.

The Kingdom envisages improving and regulating underground water resources and installing an efficient drainage network to reduce salinity in various areas.

Five research centres, dealing with fishing, insecticides, fodder, seeds, fertiliser and poultry have been set up in Jeddah, Riyadh, Jassa, Hofuf and Qatif. These centres also operate model farms.

Two hundred and fifty types of rice are being tested to cultivate 167,000 acres which will raise the production from 75,000 tons to 100,000 tons over four years.

To encourage private investment in agriculture, the government will distribute reclaimed land at an average of 32-160 acres per farmer. The farmers will be given three years to prove they are capable of tending the land satisfactorily. Otherwise, the land will be taken and given to

another more experienced farmer.

In the incentive programme, farmers will be able to purchase agricultural machinery at 55% of regular prices

The prices of imported fertilisers will be reduced by 50% and dairy equipment will be sold at 70% of their import prices.

Farmers will receive \$2.50 annually for each sheep and \$14 a year for every she-camel.

There are 17 medium-sized dams in the country and it is hoped gradually to increase these to 23. Most of the dams control rain waters in the southern region of Jaizan and Abha.

The biggest—Jaizan dam—is approximately 1,000 feet long and 125 feet high with a capacity to store enough water to irrigate 50,000 acres. It cost \$27 million to build.

Seventy million dollars were spent on the Hassa irrigation and drainage programme which increased the cultivable area around Hofuf from 20,000 acres to 50,000 acres.

Also under the plan \$51.8 thousand million was budgeted for electrification projects, desalinated water production is expected to rise from 57 million gallons a day to 163 million and a total of 270,000 new homes—some in reclaimed areas, are to be built.

Agriculture officials say that 'the days of scratching a living from small sandy plots are over for the farmers and Bedouins of Saudi Arabia'.

Vegetable production is near self-sufficiency, reports say, and the farmers who had deserted their salinity stricken farms are now returning.—*Gulf Mirror*.

cement factories supply about half of the demand of a booming construction industry; fertilisers and polyethylene bags to store them in are made on the spot.

In Bahrein, aluminium ingots are made from imported bauxite and exported. Kuwait has an aluminium smelter, clothing and household goods factories, plants making prefabricated houses and building materials. Research in hydroponics has been going on for several years, and some vegetables produced in this way now reach the market in Kuwait city.

Although one does not find on the peninsula the relatively sophisticated native technology such as is frequent in Beirut, Amman or Cairo, it should be remembered that only a few years ago, the Arab Peninsula was quite literally a scientific and technological desert. An added impetus to this awakening comes from collaboration with the poorer Arabs—Egyptians, Jordanians, Lebanese, Palestinians—

and an effort is being made to attract from Europe and particularly from the United States Arab scientists who have become established abroad, and even taken foreign nationalities. Most come on short-term contracts (a sabbatical year for instance) but a few find their ancestral land so transformed that they are tempted to remain.

There is, understandably, a problem posed by instant wealth. Although it has certainly given a boost to this 'leap' into the modern age; sometimes it becomes an obstacle by removing some of the incentive to learn in a system where not only is there no tuition but nationals receive a substantial living allowance. It seems, though, that there is a consciousness of this, and in several centres of higher learning, incentive have been set up to reward effort and achievement. Talented young Arab graduates are subsidised to continue their studies abroad, and are assured of finding a rewarding position when they return home. □

international news

MEMBERS of the House of Representatives returned to Washington from their summer vacations last week and promptly passed a bill which, according to its supporters, may save the United States as much petroleum as the entire supply from Alaska's North Slope. The key to that amazing prediction is the successful development and mass production of an electrically powered car—an idea which has been batted in recent years by plenty of rhetoric but few dollars.

The bill would provide as much as \$160 million over the next five years for a research and development effort designed to improve battery technology and to pave the way for commercial introduction of electric vehicles on a grand scale. That amount should be compared with the trifling sum of \$1.166 million which was spent by the federal government on battery-powered vehicle studies between 1969 and 1974.

Battery-powered cars are, of course, already in commercial production, but their range is limited to about 50 miles because they use conventional lead-acid batteries, which need frequent recharging. Nevertheless, as one proud owner of an electric vehicle, former Atomic Energy Commissioner Clarence E. Larson, pointed out in a letter to the *Washington Post* last week, 50 miles is quite far enough for most city trips.

The potential market for electric cars is certainly large. For one thing, it is estimated that 50% of all car journeys in the United States are less than five miles, which says a lot about unnecessary use of the automobile. A more pertinent statistic is that about 98% of all trips taken with second family cars, lie within the 50-mile range of present battery technology. The second car, which is part of the American way of life, is therefore clearly the target of the electric car industry if, or when, it is in business.

Other advantages claimed for electric cars are that since they will mostly be charged up overnight, when electricity demand is low, no new electricity generating capacity will be required. It also goes without saying that the lack of pollution from the car itself will be a good selling point. And much is also made of the fact that transportation now accounts directly for about 25% of total energy use in the United States; the potential saving in imported oil by replacing petrol-driven cars with electric vehicles is

Congress boosts electric car research

by Colin Norman, Washington

therefore immense. (But it should be noted that total energy savings will be negligible since the energy required to produce the electricity will offset the savings in petroleum. The important point, however, is that the net effect will be to shift energy consumption away from oil to coal and nuclear power.)

But the picture is not quite as bright as the most ardent enthusiasts maintain. Political, technical and economic problems could all stunt the growth of the fledgling electric car industry.

First, the costs. A study carried out by the Environmental Protection Agency, which was published last October, concluded that electric cars would be between 20 and 60% more expensive overall than equivalent conventional cars until battery develop-

ment significantly reduces battery depreciation costs. The expense of charging up the battery is only a part of the total operating costs, and some technological advances will be required both to extend the capacity of batteries and to make them more durable.

As for the range of electric cars—probably the chief commercial drawback of present models—a committee of the National Academy of Sciences estimated in 1973 that it would take at least four years, assuming adequate funding, to develop an advanced battery power plant with a range of over 100 miles. The committee estimated that it would then take an additional seven to 10 years to mass produce cars with advanced batteries. Those time scales are now considered to be optimistic, however, largely because private and public funding has not built up as rapidly as expected.

Finally, neither the automobile industry nor the oil industry have shown much enthusiasm for the electric car. Both are powerful lobbies and according to some observers they have been effective in holding up the development of battery technologies. Whatever the truth of allegations, it would certainly be a major operation for Detroit to

Pasteur Institute on way back to solvency

AFTER reviewing a report of the Pasteur Institute's financial status, Madame Simone Veil, Minister of Health, has persuaded the French government to increase credits allocated to it from some 20 million francs in 1975 to 50 million francs in 1976. This is in addition to subsidies to the institute's teaching activities, and to total or partial salaries paid to some Institute researchers by the Centre National de la Recherche Scientifique and the Institut National de la Santé et de la Recherche Médicale.

The new budget is to be approved by the parliament, but it has already been announced by the Ministry of Health and, barring the unforeseen, should be passed.

According to Dr Joel de Rosnay, director of development, the grant will ensure solvency, and enable the institute to continue its development following a businesslike reorganisation earlier this year. It covers about half of the expenses of the foundation, the research branch of the institute. The

rest will come from other resources, including interest on capital, donations, and income earned by Institut Pasteur Productions, the institute's commercial arm. (A forthcoming innovation will be the standardisation of the "mutatest" devised by Dr Bruce Ames of the University of California at Berkeley. The test relies on the ability of carcinogenic chemicals to cause mutations of strains of the common bacteria *Salmonella typhimurium*. Developed in France in collaboration with the International Agency for Research on Cancer in Lyon, it will be available commercially).

In addition, during the recent visit to France of Sheikh Sabas Al Salem Al Sabah, the Pasteur Institute received from Kuwait a donation of 5 million francs, about half of the institute's annual deficit. This donation will be used "out of budget" to finance research on infectious and tropical diseases, embryology and cancer.

—Alexander Dorozynski

Four years after its creation, the Canadian Ministry of Science and Technology is to be reorganised. News of the change was given by the Minister of State for Science and Technology, Mr C. M. Drury, at the thirteenth Pacific Science Congress. "The ministry's job has been to advise the government on how science and technology can be used and developed to the best advantage of Canada", he said. "This is a difficult task and we have learned much about the capabilities of such a horizontal ministry in the four years of its existence. Based on this experience the ministry is now being re-organised in order to enable it to function more effectively."

It will be organised at the working level to communicate with the three principal segments of the scientific community—universities, industry and government and will include the many professional and learned societies. The ministry's policy-making role was defined by Mr Drury in two categories: major continuous policy assignments with long-term implications, such as development of a national capacity to study and assess the impact of science and technology on society; and development of policies and programs for the co-ordinated and large-scale use of scientific resources beyond the scope of a single agency or government, such as the oceans policy.

"The job of the ministry", said the minister, "is not to displace or duplicate the roles of existing departments and agencies in science, engineering and technology. Nor will we try to become a sort of national oracle for science, issuing decrees on what scientists in government should and should not be doing."

● A discussion on Canadian science policy showed how far apart the bureaucrats and ordinary scientists are. While the Minister outlined precisely what science policy meant to the government, the Dean of the University of British Columbia's Faculty of Graduate Studies, P. A. Larkin, declared himself confused and be-

wildered by the concept itself—and abashed by the way in which it was being carried out. And as for communication on the subject between scientists and government, he said: "You have about as much chance of getting through as if you were reciting Gaelic poetry to a deaf seagull."

Larkin called his address "Ask Archimedes", because, he said, interest in science policy goes back a long way: "For example, Archimedes used his talents in many ways in the service of his native city of Syracuse, particularly in times of war, and presumably the king of Syracuse thus had a 'science

Science in Canada

from David Spurgeon, Ottawa

policy'—which was, 'Ask Archimedes'."

On the other hand, said Larkin, Canada's science policy for 50 years was "me too", meaning that it simply copied the policies of other countries. "And its implementation was accomplished when C. D. Howe, the 'minister of everything', played golf with C. J. Mackenzie, who, as the President of the National Research Council, was the architect of the national determination to build scientific intellectual resources."

Later, Larkin continued, many reports were published on the national scientific effort "Virtually every report by a committee or task force on science policy in the last 20 years has had something to say about the failures in coordination, communication, and integration; and the frightful sins of duplication, procrastination, and bureaucratisation. Since the most recent reports sound very like the older ones, it seems likely that either no one reads the reports or, if they do, they pay little attention."

Outlining some of the main thrusts of science policy thinking, Larkin declared himself—and others—be-

wildered. It has become obvious that so many changes are taking place so rapidly, he said, that no one has a good grasp of where we are collectively headed. "Even if someone could see it all clearly, it is most unlikely that he could do anything about it. World wide, science and technology are in a state of extremely rapid and turbulent evolution. There are so many scientists, and communications have become so good, that problems are perceived, attacked, solved and the solutions applied almost before most of us are aware of them . . . Science policy has become a curiously all-pervasive and eclectic exercise in which it is increasingly difficult to judge whether you are worrying about the right thing."

Furthermore, said Larkin, most reports concerned with science policy are obsolete by the time they are published. Few read them any more. Most are "essentially a condensed summary of a consensus that has not only been reached but partly implemented before the report is made public. With several such studies going on at once, the national capital often gives the impression of being a full time continuous scientific conference in which everybody is writing papers and no one is attending the sessions at which the papers are presented."

The committee, task forces, commissions and the senior Civil Service, said Larkin, "move along close to the margin of what almost seems uncontrollable change, documenting and formalising what has already happened, arguing a bit about who thought of it first (when none of them did), performing the apparently essential tasks of administering and reorganising, but in reality never realising they are like the bubbles in beer, produced by pressures that are quite incomprehensible."

Mr Drury called Larkin's comments about communication between scientists and government "cynical", and said that some institutions and mechanisms already existed for such communication, and that one task of his ministry was to devise other methods

switch some of its production to an entirely new automobile concept. The big car makers have, after all, raised enough complaints about the relatively minor production changes necessary to meet air pollution standards.

Those obstacles to commercial production are the chief factors which prompted the House of Representatives to approve massive federal support for a research and development effort last week. The bill, which was largely the work of Representative Mike McCormack, instructs the Energy Research and Development Administration to

devote more money to developing advanced battery technology. But the heart of the measure is a demonstration programme through which the federal government will underwrite the costs of at least 7,500 electric cars during the next five years.

The purpose of the demonstration programme, according to a report written by the House Science and Technology Committee, "is to get present and future state-of-the-art electric vehicles out into every region of the country". They will be used in federal, state and local government fleets, by

businesses and by individuals, to gain experience of driving performance, maintenance costs and so on. An important aspect of the operation, however, is that it will provide an incentive for industry to set up the production facilities, which should pave the way for mass production later.

The bill was passed easily by the House—by 308 votes to 60—and the Senate Commerce Committee will hold hearings on a similar measure early next month.

It is expected that the Senate will also pass it easily. □

Good for science?

SIR,—Your editorial "Good for people, bad for science" (July 10) requires a prompt comment, for you apparently advocate a major change in the system of academic tenure. At the same time, your editorial seems to indicate neither an awareness of the complexity of the issue, nor of experience with alternative tenure systems, nor of the considerable literature in this area; I refer here primarily to the tenure system that is very widely used in the USA, the role of the American Association of University Professors (AAUP), and the many articles and books in which this subject has been discussed.

Tenure is generally awarded, in US colleges and universities, after a probationary period that should be long enough to provide sufficient time for a reliable assessment of the capabilities and promise of a faculty member, yet should not be so short as to lead to an unacceptable proportion of bad decisions. The AAUP guideline of a maximum probationary period of seven years is widely followed, but universities will often award tenure much earlier in an attempt to hold on to younger people of exceptional ability. This does not, of course, ensure that all those who have tenure will continue to merit it, and removal for cause (including demonstrated incompetence, as decided by an elected faculty committee) is recognised, though rare.

The major benefit conferred by tenure is the freedom that faculty members should then have to study, discuss and explore without fear, views and topics that may be highly unpopular or controversial at that time. Most scientists pursue careers that are models of conformity and caution, but some may wish to be more adventurous. Research involving human subjects raises strong passions—consider the continuing debates over foetal research and genetic engineering. If these scientists were subject to renewable contracts, it is safe to predict that, for many, caution would increase as the renewal date approached, and topics that may seem of major scientific interest would be neglected if adequate protection could not be guaranteed for those who wished to work on them. These are not hypothetical fears of imaginary but unlikely situations: these pressures on the academic community exist and should be recognised.

There is another serious objection to the proposal for contracts: who would review them and make the decisions on renewal? A senior administrative officer in the university or in Whitehall? With what advice? Or a group of faculty members or the department chairman? One may reasonably claim that professional competence can only be judged by others in the same discipline, but this is more likely to lead to leniency on the part of the reviewers in the hope of similar treatment when their own renewals come up. Leaving the decision to a department head carries other risks: renewal will provide an excellent opportunity to get rid of the abrasive members of the faculty. Indeed, extensive AAUP experience has shown that a major proportion of the threats to faculty members come from other faculty members and from department heads and deans who were once also faculty members. Overall, the apparently attractive idea of renewable contracts bristles with severe problems of implementation, and should not be lightly suggested without at the same time treating this side of the suggestion.

It is not only on the frontiers of research that feelings become inflamed and faculty positions are threatened. Some of us hope that more university scientists will become engaged in what Ravetz has termed 'critical science' (*Scientific Knowledge and its Social Problems*, Oxford University Press, 1971). This involvement in current issues should not need to be partisan but can be in the direction of elucidating complex technical issues to a broader public. Here again, these scientists need the protection of tenure, for, it is clear, those employed in industrial and government laboratories do not have the freedom to engage in these issues unless they are generally on the side of their sponsors. University science departments will probably provide virtually the only source of independent comment, and these scientists will not be able to play a responsible role if their jobs are in jeopardy. Here again, this is not some hypothetical possibility: as 'critical' science has slowly developed in the USA, government and industrial scientists have been conspicuous by their silence.

Those of us who have had experience in faculty matters, with tenure and with the AAUP, recognise that the weakness of the tenure system is the

protection it extends to those who prefer to relax and do little or nothing, but most of us consider this is a modest price to pay for the many advantages. A tenure system can operate no better than those who have to make the decisions; some decisions will be good and others bad. A recent thorough examination of the tenure system (*Faculty Tenure*, Commission on Academic Tenure; W. R. Keast, chairman; Jossey-Bass Publishers, 1973) produced a strong endorsement.

In summary, then, your editorial is disappointing. Perhaps the British universities' tenure system does need overhaul; perhaps a probationary period similar to that in the USA should be considered, along with a greater involvement of the non-professional faculty in matters of faculty promotion and tenure. But I would hope that notice is taken of the extensive and documented experience before adopting a contract system that has a superficial appeal but is potentially severely detrimental to academic freedom.

Yours faithfully,

M. W. FRIEDLANDER

Washington University,
St Louis, Missouri 63130

Fellows overseas

SIR,—I can well understand the frustration felt by UK postdoctoral fellows overseas as described by Richard James (August 7). Since I doubt that the "structure of the UK University system" will change, I can perhaps do a little to put the position straight, at least as I see it from my department, and make a suggestion.

All of us want very much to appoint the best people to the few lectureships available. Our system of advertising the posts as soon as we are assured of the finance is not only efficient but is fair and should not be classified as ponderous. It would unnecessarily delay matters to set a deadline for receipt of applications which gave time for the advertisements to be seen by all potential applicants overseas. In my experience we never keep strictly to the deadline, and will always consider late applicants and give special consideration to those who are overseas. A brief airmail statement to the effect that a formal application is on the way is certainly helpful. In short I do not believe that the heads of departments handling the regrettably

small number of lectureships are unsympathetic and ponderous.

I agree that it would be better if we could all plan appointments much further ahead than we do at present. I think this is unlikely to happen in the foreseeable future. May I suggest, therefore, that it would be very helpful if overseas postdoctorals who are interested in returning here keep in touch with their former head of department and, more important, make an arrangement with a former colleague who would provide information concerning any vacancy that might be of interest.

Yours faithfully,

P. N. CAMPBELL

Department of Biochemistry,
University of Leeds, UK

Engineering standards

SIR,—In "Round Britain (July 31) you report, and seem to approve, the Committee of Vice-Chancellors and Principals' pressure to increase the academic standard of British engineers by encouraging employers to insist on higher degrees. My job is engineering design and project management in an advanced field (fast reactors), and I can sympathise with the CERN engineers who despair at the often woefully inadequate capabilities of British industry; but I should need a lot of convincing that this has anything to do with the number of years people spend at university. Most would agree that where fast reactors are concerned the ranking order of national success is France, USSR, United Kingdom, with USA, Japan and West Germany following somewhere. I am pretty certain that this does not correlate well with the national proportions of engineers holding higher degrees, but perhaps the vice-chancellors would like to give us some statistics?

Success in advanced engineering projects obviously demands a reasonable level of theoretical ability, but it depends much more on the attitudes and policies prevalent nationally and within industrial firms, and on the ability of engineers to handle unfamiliar and very complex technical and organisational problems with imagination and good judgement. I suggest that to encourage large numbers of men to spend two or three years calmly researching esoteric problems is not likely either to improve government and public attitudes to engineering or to develop the necessary flexibility in the men concerned.

For my money I would support the Open University against all the dignity of the vice-chancellors; its technology courses are designed to stimulate thoughtful, imaginative and socially responsible attitudes. It is being squeezed financially by the government

that conceived it, and it is also not yet receiving the recognition it deserves from professional bodies. In these circumstances to channel extra resources into expanding post-graduate engineering departments would be short sighted indeed; what is needed in British engineering is more excellence and public acceptance at first degree level, not more narrow specialisation.

Yours faithfully,

JOHN A. GATLEY

Knutsford,
Cheshire, UK

All at sea

SIR,—Recently (May 8) you reported on some of our work in your editorial "For those in peril on the sea". Scientists and crew aboard research vessels co-exist under tension, created mostly by the needs of scientists and felt mainly by crew; tension which can and does erupt into unpleasantness. This costly problem is now recognised by the Canadian and German governments, for example.

Our most basic finding is that this situation results from locking two warring sub-cultures—academicians and people of working-class orientation—on a ship at sea where they cannot avoid each other as on land. The single most important cause of tension is the "data hunger" of scientists and their degree of sensitivity to the relaxation needs of the crew.

Many scientists, yourself included, have criticised our findings. Unfortunately, they all did so having read only a news release (which mentioned only Bernard). Published work should be read before criticism. We question your saying, "for half the price of placing an anthropologist . . . (you) would have been happy to tell" ONR about shipboard life. The total cost was less than three days' 1972 ship time (and covered part of a larger project to describe human relations numerically).

It is important for scientists to realise that mariners' views differ intrinsically from your editorial. For example, you compare the chief scientist with a referee, and believe that captains always want to get ships to port a day early. But captains also see themselves as referees, and believe that scientists always want to get ships to port a day late. Whether any of these sentiments are true (in fact ships do dock both early and late) is irrelevant. The important thing is that these sentiments are believed by those concerned, and insensitivity by others to these beliefs causes conflict.

Anthropologists rarely learn much that the natives, like yourself, do not know. Your observations affirm some of our work. We hope to hear from

other members of the ocean science community on conditions aboard any nation's vessels. A dialogue might help prevent Bransfield-like incidents.

PETER D. KILLWORTH

Cambridge, UK

RESULTS of competition No. 1. Readers were invited to supply the minutes of an illicit seminar held by scientists somewhere in the Western world. Though we withheld judgement for as long as possible, we were finally forced to recognise that there simply wasn't a welter of witty replies held up in the post somewhere. It may have been that the subject was too baffling for many to cut their teeth on. Winner from the half a dozen entries was E. Jarvis, of Clapham, London (entry below). A further prize goes to Scott Gilbert, of Johns Hopkins University, Baltimore, for a near miss.

AMSS in session

THE Anti-Metric Society of Scientists held a meeting at a secret location in Mile End Road.

It was resolved that they would not budge an inch in their efforts to resist metrication and that they would continue to fathom out ways to circumvent its introduction. The problems were more than pint-sized but there was still much mileage in their opposition activities.

Contingency plans were drawn up to ensure that members would at least obtain their pound of flesh; an issue would be made of diamond cutters for reducing litre glasses to pints and pocket saws for cutting down metre rules to yards.

The ladies' committee announced that Valentine Cards inscribed 'I love you a bushel and a peck' would be available to members by the dozen.

Competition No. 2. An easier test this time, with a longer time limit of six weeks to allow for mental as well as postal blockages. A prize of £10 awaits the winner (or winners):

There was a young lady called Bright,
Who travelled much faster than light,
She went out one day

In a relative way,
And arrived home the previous night.

Ms Bright and her épéeist companion Fisk are already immortalised in limericks with a scientific flavour. Competitors are asked to submit further examples based, in similar vein, on fundamental scientific principles, observations and so on. □

news and views

A YEAR ago *Nature* published a communication by J. B. Barbour (*Nature*, **249**, 328; 1974) on "Relative-distance Machian theories". There were some general comments in *News and Views* (*Nature*, **249**, 305; 1974), but no discussion of details because Barbour promised another model having 'more interesting properties'. This was recently published under the title "Forceless Machian dynamics" (Barbour, *Nuovo Cim.*, **26B**, 16; 1975). It may be useful now to comment on the model without again reflecting upon wider aspects of so-called Machian concepts. This is possible only with sufficient indication of Barbour's mathematical procedure, while keeping it as concise as possible; I concentrate on his recent paper, but rely upon the earlier one for certain explanations.

Barbour considers a system of N particles of mass $m_1, \dots, m_i, \dots, m_N$, with $\sum m_i = M$, where m_i is an intrinsic number associated with particle i . They are in a three-dimensional Euclidean space; any configuration of the system may be specified by a point in $3N-3$ -dimensional space (since only relative distances are to be significant) called relative configuration space (RCS). The history of the system is a curve in RCS; a suitable parameter along the curve defines time t . Barbour assumes that the history is got by making a Lagrangian function L extremal, and a necessary consequence of his interpretation of Machian requirements is that L is a function only of the distances r_{ij} between the pairs of particles and their t derivatives. For the system of simple particles he postulates

$$L^2 = \sum m_i m_j \dot{r}_{ij}^2 / r_{ij}$$

Now, however, Barbour is interested in replacing these particles by bodies admitting some internal motion. In order to disclose the consequent possibilities, he constructs a highly particular model; it is probably the simplest that is capable of exhibiting the features to be discussed—it is certainly ingenious.

For simplicity, the model is confined to a Euclidean plane; as before, it consists of a number of masses, but here each mass m_i is a ring of radius a and uniform line density ρ_i , where $m_i = 2\pi a \rho_i$, and $a \ll r_{ij}$ for all i, j ($i \neq j$) so that r_{ij} may still be called the distance between bodies i, j . The angular coordinate corresponding to rotation of ring i about its centre is ϕ_i .

As he says, Barbour proceeds to calculate a test-particle 'situation'—

Mach in detail

from W. H. McCrea

'scenario' in the vernacular. He considers a test-ring, also of radius a , of mass $m \ll m_i$, and with angular coordinate ϕ , where the rotational velocity $\dot{\phi} = a\dot{\phi}$ and the translational velocity of the test-ring will be found to vary with its location relative to the others, but m is so small that its effect upon the motion of the others is negligible.

At time t the test ring has polar coordinates r, θ relative to some particular ring S of mass m_s , which is assumed to rotate at constant speed $a\dot{\phi}_s = c$. Then if the appropriate part of the foregoing Lagrangian is expressed in terms of elements $ap d\phi$, $ap_s d\phi_s$ of the rings m , m_s and integrated over them, they make a contribution to L^2 , up to terms in $(a/r)^2$,

$$\{\frac{1}{2}mm_s(2\dot{r}^2 + \dot{\chi}^2 + c^2)\}/r$$

For the model, Barbour further assumes all the numerous remaining rings to be distributed uniformly round a circle of radius $R (\gg r)$ with centre at S , the rings being at relative rest but all having the same rotation $a\dot{\phi}_i = c$. He finds these contribute to L^2 , to the appropriate approximation, the amount

$$\{\frac{1}{2}mM(\dot{r}^2 + r^2\dot{\theta}^2 + \dot{\chi}^2 + c^2)\}/R$$

According to his postulates, the motion of the test ring is obtained by treating the sum of the two contributions as the effective Lagrangian \bar{F} , dividing for convenience by the constant M/R . For a well known property allows us to use \bar{F} instead of its square root, provided the variable t has been suitably normalised. The Lagrange equation in χ then gives

$$\partial \bar{F} / \partial \chi = \chi + B\chi = K$$

where $B = Rm_s/rM$, and K is a constant.

At this point Barbour assumes $K=c$, and he takes $B \ll 1$ as it is in his application. Then by further appeal to standard theory of variational principles, he shows an equivalent Lagrangian \tilde{F} for r, θ to be, to the required approximation

$$\tilde{F} = (\dot{r}^2/2) + (r^2\dot{\theta}^2/2) + (Rc^2m_s/Mr) + (Rm_s\dot{\phi}^2/Mr) - c^2(Rm_s/Mr)^2$$

In order to give the model a tentative

physical meaning, Barbour identifies the particular ring S with the Sun, the test-ring with a (small) planet, the distant rings with the rest of the universe. He can then identify R, M with the conventional radius and mass of the universe, and then he quotes the 'cosmic coincidence' that the Newtonian cosmological constant $G \approx Rc^2/M$, provided c be taken as the speed of light. Then in \tilde{F} the first two terms are the inertia terms and the third the gravitation term in the Lagrangian for a particle moving in the field of a mass m_s according to Newtonian mechanics and gravitation. So Barbour considers he is on the track of an explanation of inertia and gravity "in terms of the single simple concept of mass in relative motion" and that this "hinges on the existence of the conjectured internal motion." The latter he would naturally expect to be more complicated in a more realistic model. He goes on to speculate on the possibility that "the rest-mass energy of the particles is associated with an incessant internal motion at velocity c ", so that the internal motion would account for both inertial and gravitational mass. He hopes for a generalisation of his Lagrangian that could be regarded as comprehending special relativity and quantum mechanics.

The last two terms in \tilde{F} are what Barbour calls (small) Machian terms. He states that the corresponding terms in the analogous three-dimensional model yield one-sixth of the Einstein value for the advance of the perihelion of a planet. Presumably he hopes for a better value in a more developed treatment, and he mentions several other expected developments. Lastly he suggests that his treatment may be regarded as a realisation of a system of forceless dynamics envisaged by Hertz but never constructed.

It is easy to ask several questions: Can the treatment be applied to other obvious problems? What is the status of the geometry and of time in the theory? What is the justification for the use of a variational principle and for the Lagrangian employed? Has it a meaning to say that all energy may be kinetic since, if there is no rest mass, we ask what carries the kinetic energy? Also there are questions of detail: For example, why does Barbour identify his constant K , which is a constant of a particular motion, with c which appears as a universal constant in his scheme?

Nevertheless, at this stage the work is clearly exploratory and one should ask rather what promising positive indications are emerging. It is certainly so

interesting that one must wait at least to see what Barbour will do next. It might prove to be just another way of developing general relativity, or it might yield general relativity with certain constraints that render it Machian in

some sense in which general relativity is not necessarily Machian. Or, as Barbour seems chiefly to hope, it may give something like Machian relativity incorporating some sort of quantum mechanics. □

Synaptic remodelling in the mutant cerebellum

from Shin-Ho Chung

OVER the past few years, anatomical studies on neurological mutant mice have shed new light on the mechanisms governing the formation of the mammalian nervous system. In particular, the cerebellar cortex of these mutants has proved to be fertile ground for investigating certain fundamental questions about neural development. This is because the cell types and their interrelationships, along with the normal sequence of developmental processes, are better understood in the cerebellum than in most other parts of the nervous system. Because a single gene mutation often interferes with developmental processes in a precise and specific way, examination of the affected brain will reveal the primary target of the mutation as well as the consequences of such a previous mistake on the subsequent formation of the brain. A recent ultrastructural study on the 'weaver' cerebellum by Sotelo (*Brain Res.*, **94**, 19-44; 1975) is aimed at elucidating these questions.

The cerebellum of the normal mouse contains six types of neurones distributed in three layers; these are, from the outside in: the molecular layer, the Purkinje cell layer and the granular layer. The cells interconnect in regular patterns and integrate the inputs conveyed from other parts of the brain by two main afferent fibre systems. The Purkinje cell bodies which lie in a single row just above the granular layer, extend their flattened dendritic trees towards the surface of the cerebellum. Climbing fibres, one of the two main inputs to the cerebellum, form numerous synaptic contacts with the shafts of these Purkinje cell dendritic trees (see figure). The second input (mossy fibres) influence the Purkinje cell mainly through granule cells. Profuse branches of the granule cell dendrites curve around and encapsulate the expanded terminal of a mossy fibre, forming a tangled ball of dendrites and axons. Axons of the granule cells, known as parallel fibres, are extended towards the molecular layer, where they bifurcate, and running perpendicular to the Purkinje cell dendrites,

form numerous synapses with their spiny branchlets.

When this intricate structure is severely perturbed, as in the homozygous weaver mouse, the animal exhibits behavioural abnormalities characterised by tremor, hypotonia and ataxia. The autosomal, recessive weaver gene mutation arose spontaneously, and subsequent histological examination of the affected animal revealed that almost the entire population of granule cells is missing (Lane, *Mouse News Lett.*, **30**, 32; 1964). During postnatal development of the normal mouse, postmitotic granule cells migrate down from the germinal layer (near the surface of the cerebellum) through the Purkinje cell layer to form the granular layer. Rezaei and Yoon (*Devl Biol.*, **29**, 17; 1972) first showed in the homozygous weaver mutant that granule cells proliferate normally, but remain at the germinal

layer and gradually die. From these observations, Rezaei and Yoon suggested that the massive cell death is a consequence of the failure to migrate.

This conclusion was supported by subsequent investigations. In a series of electron microscopic studies, Rakic and Sidman (*Proc. natn. Acad. Sci. U.S.A.*, **70**, 240; 1973; *J. comp. Neurol.*, **152**, 103, 133; 1973) noted that the disorder is accompanied by defective Bergmann glial fibres. It had been shown previously that these glial fibres guide the migration of the granule cells into the granular layer (Rakic, *J. comp. Neurol.*, **141**, 283; 1971). Early in development, before the granule cells have divided, numerous glial cells extend their Bergmann fibres radially towards the external granular layer. The postmitotic granule cell then attaches itself to the endfeet of the glial fibre to descend to the inner region of the cerebellum, while undergoing an ordered series of transformations in shape as it migrates. As the cell body descends, it leaves a T-shaped axon behind, which is to become a parallel fibre. Thus, in order to move across a complex terrain that changes in composition with time, migrating granule cells use the Bergmann fibre as a sliding ladder. Rakic and Sidman believe that the target of the weaver gene mutation is the Bergmann glial abnormality which causes, and precedes, failure to migrate and the death of granule cells. As evidence for this assertion, they note that the glial abnormality can be detected long before the

appearance of granule cells, and that migration is slowed along the abnormal glial fibres in heterozygotes. Moreover, morphological examinations show no difference in the granule cells of normal and weaver mice before they start to migrate. Sotelo and Changeux (*Brain Res.*, **77**, 484; 1974), however, dispute this conclusion. In the homozygous animal carrying the weaver mutation but with a genetic background different from that of the mice studied by Rakic and Sidman, they find that Bergmann fibres appear almost normal. This was also found by Bignami and Dahl (*J. comp. Neurol.*, **155**, 219; 1974) who studied the development of Bergmann fibres in various neurological mutants using an immunofluorescence technique. Furthermore, the few granule cells that do migrate successfully undergo a similar course of degeneration as the postmitotic cells that fail to migrate.

Although the primary target of the genetic abnormality thus remains unsolved, its consequences on synaptogenesis have been analysed by Sotelo (1975) and Rakic and Sidman (*J. comp. Neurol.*, **152**, 103, 133; 1973). Because mutant cerebellum is agranular, the mossy fibre is deprived of its normal postsynaptic target, and apical dendrites of the Purkinje cell lack the afferent terminals which would occupy these synaptic sites. Probably because of the existence of unoccupied synaptic sites calling for innervation, there is an extensive remodelling of the cerebellar circuitry, as well as reshaping of the dendritic geometry. Instead of assuming the normal pattern of the dendritic tree with profuse tertiary branches, the Purkinje cell dendrites are oriented haphazardly and their thickened primary and secondary branches, without the usual spiny branchlets, continue to grow to the pial surface where they may turn inward. By contrast, the Purkinje cell dendrites in normal animals seem to recognise some kind of invisible barrier that excludes them from penetrating into the external granular layer. These aberrant, even inwardly oriented, dendrites are nevertheless entwined faithfully by climbing fibres, but their apical segments which are normally occupied by parallel fibres are frequently innervated by climbing fibres also. Failing to find their proper targets, mossy fibres extend their terminals and penetrate towards the superficial half of the cerebellum. The endings may then be encapsulated by dendrites of other types of neurone with which they normally do not form exclusive synaptic junctions.

These observations highlight some of the unsolved problems in neurobiology. The development of the nervous system involves a number of events

occurring in sequence. From the germinal layer, neurones migrate to their eventual destinations and extend dendritic and axonal arborisations characteristic of each cell type before functional connections are made between one neurone population and another. Since the cerebellar disarray in the weaver mouse results from the failure of granule cells to migrate, other neurones should be normal in appearance if their properties are determined solely by intrinsic epigenetic mechanisms. That the shape of Purkinje dendrites is drastically altered, and mossy and climbing axons extend their processes further than they normally do, suggests the importance of an interaction between a neurone and its milieu in the moulding of the nervous system. Moreover, the observation that synaptic contacts can be formed in the weaver cerebellum between pre- and post-synaptic elements which normally do not form junctions, shows that intrinsic specificity for afferent-efferent coupling can easily be overridden by an altered environment. Such a flexible strategy in the developmental programme is indeed one of the ways of minimising the effects of a previous mistake, genetic or epigenetic, in the subsequent formation of the nervous system. □

Thermodynamic errors by international commission

from D. R. Wilkie

ALAS, the gulf still seems wide between some branches of physiology and the base of physical chemistry on which biology must ultimately rest. Even so it is hard to understand how a distinguished international group comprising 11 physiologists (after consultation with 57 others) came to put forward recommendations that are simply at variance with the laws of thermodynamics. Even more remarkable, these recommendations have apparently remained unchallenged for the one and half years since they were first published, suggesting that confusion about this topic is indeed widespread.

The International Commission of the IUPS for Thermal Physiology has published detailed recommendations concerning the names and units to be employed by physiologists engaged in studying metabolism, thermal balance, and so on (Bligh and Johnson, *J. appl. Physiol.*, **35**, 941; 1973). This is a praiseworthy enterprise, and the Commission has made one or two radical recommendations, the most striking (page 941) being

that "In the BODY HEAT BALANCE EQUATION, the symbol M is now used to denote METABOLIC FREE ENERGY PRODUCTION; METABOLIC HEAT PRODUCTION is identified by the symbol H ". By "free energy production" is clearly meant the rate of change of free energy associated with the chemical processes of metabolism, taken with a negative sign. This new definition has much to commend it since it is the changes of free energy, rather than of energy or enthalpy, that determine the potentiality of chemical reactions to drive the processes essential to life—such as biosynthesis and thus growth, production of electrical or mechanical work, and active transport.

The proposal is somewhat idealistic since free energy changes are usually difficult to measure. There are abundant calorimetric determinations of the energy and enthalpy changes associated with the oxidation of foodstuffs, but I at least do not know of similar systematic determinations of free energy changes since the pioneering work of Burk (*Proc. R. Soc.*, **B104**, 153; 1929) who showed for the oxidation of carbohydrate that the free-energy change was almost equal to the enthalpy change. It cannot be assumed that the same near equality applies for the oxidation of other foodstuffs: and it certainly does not apply for other important metabolic reactions such as the hydrolysis of ATP. In any case, when one is concerned purely with questions of energy balance (as in most of thermal physiology), the free energy change is not directly relevant. Confusion over this point has led to the incorrect equation (recommendations page 943):

"BODY HEAT BALANCE EQUATION: A mathematical expression that describes the net rate at which a body generates and exchanges heat with its environment (First Law of Thermodynamics):

$$S = M \pm E - (\pm W) \pm R \pm C \pm K$$

[W] or [W m⁻²]

in which

S = rate of STORAGE OF BODY HEAT (+ for net gain by body)

M = METABOLIC FREE ENERGY PRODUCTION (always +)

E = EVAPORATIVE HEAT TRANSFER (− for net loss)

W = WORK (+ for POSITIVE WORK against external forces)

R = RADIANT HEAT EXCHANGE (+ for net gain)

C = CONVECTIVE HEAT TRANSFER (+ for net gain)

K = CONDUCTIVE HEAT TRANSFER (+ for net gain)."

This equation is incorrect. It is compatible with the First Law only if one substitutes for their definition of M :

" M = the total rate of change of enthalpy resulting from the chemical processes of metabolism, taken with a negative sign".

I have since confirmed in a helpful correspondence with Dr Bligh that the Commission was not fully aware of the fundamental distinction between 'free energy' and 'energy' or 'enthalpy'. Clearly it will take some time to frame modified recommendations that do take account of this difference: meanwhile the recommendation quoted from page 943 (and others derived from it on pages 949, 950, 951 and 958) should be interpreted with great caution.

Basically the relation between the chemical processes of metabolism and their physical manifestations, work produced (w) and heat produced (h), is perfectly simple, (Wilkie, *Prog. Biophys.*, 10, 260; 1960). In modern terminology we have, under strictly isothermal conditions, over a defined time interval Δt :

$$h + w = \Delta \xi_1 (-\Delta H_{m1}) + \Delta \xi_2 (-\Delta H_{m2})$$

and so on

$$= \sum_0^j \Delta \xi_i (-\Delta H_{mi}) \quad (1)$$

where the subscripts 0– j designate the various chemical processes occurring; the $\Delta \xi_i$ represent the extents by which each reaction has advanced (measured most conveniently as additional mol of a named product that have appeared); and the ΔH_{mi} are the molar enthalpy changes of the various reactions measured calorimetrically and expressed in kJ per mol of the same named product formed.

Note that if the organism is in a steady state—and the experimental design in most metabolic studies aims to achieve this—the situation becomes very simple indeed since the $\Delta \xi_i$ of all the intermediary reactions are then zero. If only a single substrate (carbohydrate for example) is being oxidised the right hand side of equation (1) then becomes reduced to a single term (Wilkie, *J. Mechanochem. Cell Mot.*, 2, 257; 1974). At first sight this may seem surprising since the intermediary reactions are still proceeding and contributing to the heat produced. That they are equivalent to a single global reaction is a consequence of Hess's Law.

Thermal physiologists are generally not interested in strictly isothermal conditions since they are concerned with what happens when the body temperature θ changes. They are also concerned with the various ways in which heat can be transferred from the body to the environment by evaporation (e), by radiation (r), by convection (c) and by conduction (k). Equation (1) can be readily adapted for this purpose. Rearranging into roughly the same form as that quoted from the recommendations:

$$C\Delta\theta = \sum_0^j \Delta \xi_i (-\Delta H_{mi}) - w - e - r - c - k \quad (2)$$

C is the thermal capacity of the body (SI unit $J^\circ C^{-1}$) so the left-hand side is the change of thermal energy, the "storage of body heat". All the terms in the above equation are quantities of energy (J); each can be converted to power (W) by dividing by Δt .

Note that when work is done on the organism rather than by it (so-called "negative work") w simply appears in Equations (1) and (2) with its sign changed.

Consequently there seems to me to be no need to introduce the distinction between "TOTAL HEAT PRODUCTION" and "METABOLIC HEAT PRODUCTION" presented in the recommendations; it merely confuses further a

situation that is already confused enough.

One final point of criticism is that I think that the Commission showed poor judgement in endorsing the use of the phrase "energy metabolism" (pages 946 and 951). It would be far safer to restrict the word "metabolism" to the chemical events in living organisms so as to maintain a clear distinction between the chemical changes and the changes of physical energy that result from them. This is not merely a matter of semantics. Confusion by physiologists over this distinction has recently provoked the misguided suggestion (Banks and Pearce, *Lancet*, i, 811; 1975) that energy changes are irrelevant in considering metabolic processes. □

More new particles

from W. Toner

Two remarkably long-lived new particles were discovered last November: the ψ (mass 3,095 MeV), alias J; and the ψ (3,684). At least two new states related to the ψ s, have now been observed in detailed studies of the decays of the ψ

(3,684), and it begins to be possible to sketch a tentative level scheme, as shown in the figure. A preliminary report of these studies was given in *News and Views* for August 21.

The evidence for the state named P_c comes from a group working at the electron-positron storage ring DORIS, in Hamburg and is discussed in a paper by Braunschweig *et al.* (*Phys. Lett. B*,

Tentative level scheme (July/August 1975). Only a small fraction of the decays have been identified, and only a few of those are shown. The 3,095, 3,684 and 4,200 are formed directly in electron-positron annihilation. P_c may (or may not) be the same as χ (3,530).

57, 407; 1975). They have shown that a few per cent of ψ (3,684) decays lead to the formation of the ψ (3,095) by the emission of two γ rays. They also have data which strongly suggest that the decay proceeds through an intermediate state (or cluster of states) which they have called P_c . At present they do not know whether the more energetic of the two γ rays is emitted first or second, so that their mass determination is ambiguous.

The states named χ in the figure were discussed at the recent Lepton-Photon Symposium at Stanford by Feldman *et al.*, the Stanford-Berkeley collaboration working at the SPEAR ring in Stanford, California. This group discovered the ψ (3,095) (simultaneously with Ting, at Brookhaven, who called it the J) and the ψ (3,684). They observe that a few tenths of a per cent of ψ (3,684) decays proceed by the emission of a γ ray and two, four or six strongly interacting charged π and K mesons. In the decay ψ (3,684) $\rightarrow \pi^+ \pi^- \pi^+ \pi^- \gamma$, the four pions form one or other of two very distinct states χ (3,530) and χ (3,410) whereas in ψ (3,684) $\rightarrow \pi^+ \pi^- \gamma$, the two pions form only the lower state, which is narrow (that is, long-lived). Both states appear to be formed in the 6π and 2π 2K channels. The upper state is broad, and may be a group of states. It may (or may not) be the same as P_c .

The discovery of these states ends a period of uncertainty about the general nature of the mechanism which gives the ψ s their remarkably long lives. Any explanation invoking a new quantum number whether 'charm' or 'colour' or something else inevitably required there to be a complex set of states, some of which could be reached by the emission of a γ ray from a ψ . Indeed, most models predicted much greater radiative decay rates than are observed, and inspired the earlier fruitless searches at lower sensitivity which gave rise to the uncertainty. Now that they have been seen, 'charm' is once again a hot favourite, and a multitude of detailed models is being developed in which the 'obvious' decay modes are suppressed by one subtlety or another. In these models, the ψ s, χ s and P_c though made of a charm-anticharm pair of quarks have charm = 0. Overtly charmed particles with charm = ± 1 would have to be produced in pairs. Again, fruitless searches have been carried out for theoretically obvious decay channels, and the models are now being adjusted accordingly. Colour enthusiasts have not yet given up, and of course, it could be something else altogether.

The experimenters need not involve themselves in the theoretical controversy and are being careful about the precise wording of their interpretations. For example, the broad? (4,200) state shown in the sketch is not claimed as a particle

by the Stanford-Berkeley group. They describe it as an enhancement which could be one or more new particles or, possibly, an effect connected with the threshold for some other new phenomenon. They are assured that their data—and they have a great deal more in the course of analysis—will have the last word. □

The peptide hormones: molecular and cellular aspects

from D. G. Smyth

Biosynthesis and release of secretory hormones formed the subject of a Symposium arranged by the Ciba Foundation in honour of Sir Frank Young (London, June 30–July 3). The proceedings are to be published in full by Associated Scientific Publishers, Amsterdam.

It is beginning to be accepted that most if not all peptide hormones are biosynthesised as fragments of larger molecules. The search is now on for the ultimate precursors, synthesised on the ribosome and translated from messenger RNA. J. F. Habener (Massachusetts General Hospital) described the primary biosynthetic form of parathyroid hormone, the 'preparathyroid hormone', which contains a peptide of 31 amino acids attached to the N-terminus of the 84-residue hormone. The major part of the extension, comprising the first 25 amino acids, is excised shortly after biosynthesis and before transference of the 90-residue prohormone to the secretory granule. The existence of an analogous precursor to insulin, a preproinsulin, was strongly supported by the experiments of M. A. Permutt (Washington University) who isolated RNA from catfish islets and observed its ability to stimulate protein synthesis in a wheat germ cell-free system: among the proteins formed was a major component with a molecular weight of 11,000, larger than catfish proinsulin. The *in vitro* synthesised product shared antigenic determinants with catfish insulin and appeared to be identical with a rapidly labelled protein synthesised by the islet tissue. From mammalian pancreas the isolation of mRNA has proved more difficult because the islets comprise only 1% of the tissue and ribonuclease is highly active. D. F. Steiner (University of Chicago), working with a microsomal fraction from rat islets, concluded that the signal peptide must be detached from the preprohormone on the ribosome before the proinsulin

chain is completed. He suggested there may be two distinct enzyme-catalysed steps in the export of secretory hormones, the pre-processing stage which does not involve a trypsin-like enzyme and the pro-processing stage which does. The conversion of some prohormones to hormones, however, may involve enzymes with specificities different from trypsin, and activation may take place not by hydrolysis but by aminolysis of the peptide chain (D. G. Smyth, NIMR, Mill Hill). This transamidation reaction would account for the origin of the C-terminal amide that is a characteristic feature of many of the peptide hormones and both the known releasing factors. On this basis it would be predicted that LHRF, TRF, gastrin, oxytocin, vasopressin, secretin, α -MSH, and others, will be found to arise from prohormones or pro-releasing factors that extend from the C-terminal residues.

β -MSH

The fragments formed by enzymic activation of a prohormone are retained in the secretory particle of the gland. From pig pituitary, β -MSH and two novel peptides were isolated in equivalent amounts; the three peptides represented contiguous fragments of the 91-residue polypeptide termed β -LPH and appear to have been released by an enzymic mechanism similar to that involved in the activation of proinsulin (A. F. Bradbury, D. G. Smyth and C. R. Snell, NIMR). On this evidence, it was proposed that β -LPH is the prohormone of the lipolytic hormone β -MSH. Final proof of the relationship between β -MSH and β -LPH will be obtained by isolation of the prohormone from the secretory granule and study of its conversion by granular enzymes. It is of interest that β -LPH and its 58-residue fragment γ -LPH, which are only weakly active as lipolytic agents, are present in substantial quantity in pig pituitary and this raises the possibility that the enzymic release of the hormone from these precursors may be under physiological control. Lesley Rees (St Bartholomew's Hospital) reported that β -MSH could not be detected by immunoassay of human pituitary extracts and maintained that in the human the physiological significance of this hormone is in question.

ACTH

Precursors to several hormones have been indicated by immunoassay of glandular extracts or plasma (Rosalyn Yalow, Veterans Administration Hospital, Bronx). The high sensitivity of the method allows analyses to be performed on serum from a single individual but inevitably the conclusions drawn are limited to assessments of

molecular size and convertibility of the products. A 'BIG' ACTH was found in tissue extracts of carcinoma primary to or metastatic from the lung. Excluded from Sephadex G50 and with low corticotrophic activity, 'BIG' ACTH was converted by controlled tryptic digestion to a product with high activity, apparently identical in size and charge to (1-39)-ACTH. Curiously, an intermediate size ACTH seems to be present in rabbit, rat and mouse whereas the usual 39-residue peptide predominates in other species. Yalow suggested that the hormonal form of ACTH may be a factor in regulating the cortisol:cortisone ratio in mammalian corticoid secretion. Working with pig pituitary, Bradbury *et al.* (NIMR) isolated and sequenced a new 38-residue peptide which was present in large amounts; they considered that it may be part or all of the N-terminal region of a prohormone to ACTH.

Gastrin

A 'BIG' gastrin, predicted by S. A. Berson and Rosalyn Yalow, has now been isolated from antral mucosa or

Zollinger-Ellison tumour tissue (R. A. Gregory, Liverpool University) and its sequence determined. In this precursor, a heptadecapeptide extends from the N-terminus of the 17-residue hormone and, as with the prohormones of insulin, glucagon, PTH and β -MSH, it is clear that activation is by enzymic cleavage at the C-terminal side of paired basic residues. The list of gastrins and gastrin precursors has grown to include component 1 (Cl), 'big big' gastrin (BBG), 'big' gastrin (BG, 34 residues), little gastrin (LG, 17 residues) and minigastrin (G, 13 residues); all these are duplicated by corresponding forms with sulphated tyrosine. In addition, it is known that the C-terminal pentapeptide retains full activity.

Hormone activity regulation

P. J. Randle (University of Bristol) suggested that the regulation of hormone activity may take place not by control of the rate of enzymic attack on a prohormone but by alteration of specificity. Covalent modification of certain enzymes by phosphorylation,

which is sensitive to calcium, could lead to the formation of prohormone fragments that differ in size, potency, and possibly in duration of action. In general, the conversion of prohormones to hormones is being found to take place by way of numerous intermediates, some stable some transient. Only when these have been isolated in homogeneous form and subjected to biological scrutiny will the ground be cleared for understanding the physiological role of each component.

In the closing presentation, J. R. Tata (NIMR) called attention to two classes of response initiated by peptide hormones. Rapid responses involve change in permeability in the membranes of target cells, directly affecting the levels of intracellular intermediates; slower effects take place through stimulation of RNA and protein synthesis. It seems likely that different classes of hormone receptor are concerned. Tata proposed that the ultimate expression of growth and maturation results from the cooperative interaction of the two types of response. □

DESPITE the availability of undisturbed sites, the arctic tundra has, until recently, been one of the most understudied of the world's terrestrial biomes. Even now there are many leading questions concerning general ecosystem function and balance within this biome which remain unanswered. Studies of primary production by arctic ecosystems, both in the field and in the laboratory, have been receiving some attention recently, for example by Larry Tieszen at Barrow, Alaska (*Arctic and Alpine Res.*, 4, 307; 1972, and 5, 239; 1973) and results have now been published of a carbon dioxide flux study which has been undertaken at the same locality by Coyne and Kelley (*J. appl. Ecol.*, 12, 587; 1975).

The study of carbon dioxide flux between soil, vegetation and the atmosphere has certain useful attributes as a method of approaching gross ecosystem energetics. In particular it avoids the problems of extrapolating from small samples studied in detail, either by cropping, or by CO_2 exchange studies in enclosed conditions, or by $^{14}\text{CO}_2$ incorporation studies. The analysis of data obtained is difficult, however, because of both the meteorological and the biological variables involved. In effect, a flux of CO_2 from ground to atmosphere means that respiration of producers, consumers and decomposers exceeds photosynthetic consumption at that point

in time. The reverse is true if CO_2 flux is from atmosphere to vegetation.

Coyne and Kelley worked through an arctic growing season (mid-June until the end of August) and regularly took air samples at five heights

Carbon dioxide flux in arctic ecosystems

from Peter D. Moore

up to 16 m, which they analysed for CO_2 concentration using infrared gas analysis. They also monitored various micrometeorological variables, such as wind speed, light and air temperature. For much of this season, the ecosystem received light for a full 24 h (diurnal variation, about 50 W m^{-2} at night to 250 W m^{-2} at mid-day). Diurnal air temperatures varied from 4 to 24°C . CO_2 flux also varied diurnally; on July 21, midnight values were about $-0.2 \text{ g m}^{-2} \text{ h}^{-1}$ (that is, flux from ground to atmosphere), and at mid-day, about $+0.6 \text{ g m}^{-2} \text{ h}^{-1}$. For about 17 h of the day in late July there was a positive flux of CO_2 from the atmosphere to the vegetation. For the remaining 7 h, photosynthesis failed to consume all of the CO_2 produced by ecosystem respiration. In late June and early August, the negative flux periods

were of 12-14 h duration per day. In these early and late season times, there was a daily net flux of about $-1 \text{ g CO}_2 \text{ m}^{-2}$. In the height of the season daily net flux was $+8 \text{ g CO}_2 \text{ m}^{-2}$.

Over the entire season (61 d), it was calculated that $626 \text{ g CO}_2 \text{ m}^{-2}$ was generated by ecosystem respiration. This would largely be due to the primary producers and the decomposers, the latter also responding to raised temperatures by increased activity. During the season $146 \text{ g CO}_2 \text{ m}^{-2}$ (net) was consumed by primary producers in photosynthesis; thus gross production would amount to $772 \text{ g CO}_2 \text{ m}^{-2}$. If one applies the crude conversion factor from CO_2 incorporated to dry weight accumulated of 0.614, then this represents 474 g m^{-2} dry matter (gross) in a season. The net production figures compare reasonably with Tieszen's values obtained by more conventional methods, which lends credibility to the data derived from these flux studies.

This new approach has thus provided further information concerning the consumption and generation of CO_2 in the tundra ecosystem. If the ecosystem is in a stable, equilibrium state, then one must assume that the net seasonal gain of $146 \text{ g CO}_2 \text{ m}^{-2}$ is either being returned to the atmosphere by off-season decomposition or is accumulating as litter or peat within the system.

Interstellar dustmen's convention

from Ant. Whitworth

A workshop on Interstellar Grains was organised by University College Cardiff at Gregynog Hall on July 11-13.

DUST gets into everything, or so they always say, and certainly it seems the cosmos is no exception. In astrophysics, dust grains (sub-micron sized particles constituted of compounds of Si, C, N, O, Fe, Mg) are continually invoked, and invested with new capabilities, to explain puzzling observations. Yet the recent increase in constraints on dust models has not resulted in a more definite picture of dust grains, but rather in the introduction of more free parameters (such as multi-component models and localised variations). Nevertheless, a pattern emerges, and with it the realisation that grains have many very fundamental roles in the cosmos.

At the recent workshop H. C. van de Hulst (Sterrewacht, Leiden) stressed that the interstellar medium is a very hostile environment for grains; and J. M. Greenberg (Sterrewacht, Leiden) pointed out the need to consider how intense irradiation may modify grain properties. J. P. Bibring (Laboratoire René Bernas, Orsay) has investigated grains in lunar and meteoritic samples, and concluded that irradiation of grains in circumstellar environments—say by stellar winds, energetic photons, or cosmic rays during their formation—may significantly round the grain and amorphise its internal structure. D. R. Huffman (University of Arizona, Tucson) pointed out that this bears on the identification of the $10\text{ }\mu\text{m}$ feature in infrared spectra which requires amorphous silicates; whereas the $2,200\text{ }\text{\AA}$ ultraviolet feature requires well-ordered graphite. S. Ramadurai (Institute of Astronomy, Cambridge) argued that carbonaceous chondrites contain interstellar graphite grains from the protosolar nebula, as evidenced by their anomalously high boron content, which is attributed to cosmic ray bombardment of graphitic carbon.

But a cogent case was made by N. C. Wickramasinghe (University College, Cardiff) for considering grain materials with a volatility intermediate between the very volatile 'dirty ices' (hydrides of C, N and O), and the more refractory silicates and graphite. He cited organic polymers, and in particular suggested that conditions in dark clouds may favour condensation of the widespread formaldehyde mole-

cule into elongated grains of polyoxymethylene (POM). There remains outstanding the problem of producing sufficient formaldehyde, but there is already good evidence in support of the general thesis. D. A. Mendis (University of California, La Jolla) reported on the physical parameters for the grains producing 10 and $18\text{ }\mu\text{m}$ features in comets, and indicating an evaporation temperature $\sim 500\text{ K}$: this rules out silicates, but is very compatible with many polymers, including POM. B. Thomas and co-workers (University of Wales Institute of Science and Technology, Cardiff) have measured strong absorption bands around 10 and $18\text{ }\mu\text{m}$ in thin films of POM.

M. J. Barlow (Sussex University) proposed a resolution of the problem of supplying sufficient refractory grains to the interstellar medium: refractory grains condense in almost every stellar mass loss situation, and are probably only destroyed by direct involvement in star formation after a mean lifetime $\gtrsim 10^9\text{ yr}$. D. P. Gilra (University College, Cardiff) deduced the existence of a temperature minimum in the atmospheres of late N-type carbon stars where SiC_2 grains are condensing. C. D. Andriess (Sterrewacht, Roden) presented infrared observations of η Car as evidence of dust suddenly condensing in the mass outflow at a radius $\sim 0.03\text{ pc}$. H. Okuda (Kyoto University) interpreted polarisation data on VY Can Maj in terms of a circumstellar dust disk: is this disk protoplanetary? J. Silk (University of California, Berkeley) prescribed a scenario for fragmenting and reconstituting dust in cocoons around newly formed massive stars.

W. W. Duley (York University, Ontario) offered new hope for identifying the diffuse bands: he attributed narrow lines to impurities in the bulk grain material, and the adjacent broader features to the same impurities in grains which are so small that their lattice constant is altered. D. P. Gilra (University College, Cardiff) calculated infrared absorption cross sections for small ellipsoidal particles, taking account of surface modes, and stressed the great importance of grain shape. A. P. Whitworth (University College, Cardiff) argued that in neutral clouds dielectric grains are charged stochastically on a time scale $\sim 10^3\text{ s}$, typically having 0, ± 1 electron charges. Consequently, grains are effectively untied from the magnetic field, can move through the gas under gravity and/or radiation pressure, and can be aligned in the required sense. P. A. Aannestad (University of Arizona, Tucson) suggested that stochastic grain charging may also enable grains to deplete C^+ , N^0 and O^0 equally, as inferred from observation. But D. A. Williams (Uni-

versity of Manchester Institute of Science and Technology) concluded that the depletion of CNO may anyway be negligible.

A number of interesting roles have been suggested for grains in cosmology. A. J. R. Prentice (University of Oxford) argued that in the rotating protosolar cloud, grains fall to the centre creating a core sufficiently massive to stabilise the rest of the cloud, and establishing composition gradients which will explain the solar neutrino deficiency. I. P. Williams (Queen Mary College, London) has shown the basic part which grains may play in forming the planets and determining their different compositions. M. Rowan-Robinson (Queen Mary College, London) poses the question: is dust always associated with violent events in galactic nuclei? One might also ask whether such events are not a major source of the dust in the cosmos. \square

Galaxy formation

from Janet E. Jones

A workshop meeting on "The Formation and Evolution of Galaxies" was held at the Institute of Astronomy, Cambridge, on August 4-8, and supported by the Gravity Research Foundation.

LEAVING aside the still controversial topic of the origin of pre-recombination density inhomogeneities, the emphasis at the workshop was focused on later epochs, with theories for early galactic evolution and observational "clues" on the topic being well discussed. The workshop opened with a number of papers on the covariance and multiplicity functions, the purpose being to use the presently observed spatial distribution and luminosity functions of galaxies as indicators of the primordial density fluctuation spectrum.

It was pointed out that non-linearities would tend to increase the ultimate slope of the covariance function, thus making it more difficult for an initially flat, $n=0$ (Poisson), density fluctuation spectrum to account for the observed covariance function: an $n=-1$ initial spectrum seems to give a better fit (J. R. Gott and M. Rees, Institute of Astronomy, Cambridge). Moreover, the slope of the covariance function seems to depend on galaxy type, being steeper for ellipticals than for spirals (M. J. Geller, Harvard University). This could suggest some difference in the primordial density fluctuation spectrum leading to the two types, although later attempts to model galactic evolution did not incorporate this property. In-

deed, a notable non-feature of the workshop was the absence of any attempt to propose a genuine bifurcation scheme for elliptical versus disk-like galaxies. P. Schechter (Institute for Advanced Study, Princeton), W. Press (Princeton University), Gott and Geller all discussed aspects of the multiplicity and luminosity functions for galaxies. The multiplicity function for the Gott-Turner groups of galaxies seems to be consistent with an initial Poisson density fluctuation spectrum (Schechter), although, as with the covariance function, an initial $n = -1$ spectrum gives a slightly better fit (Gott).

B. Jones (IOA, Cambridge) reviewed turbulence theory for the origin of primordial density perturbations, and discussed the effect of the recombination process on the covariance function derived from both the cosmic turbulence theory and the adiabatic density perturbation theory. This, and a later more specialised discussion by S. Bonometto (University of Padua), emphasised some of the difficulties inherent in both these theories for the origin of primordial density inhomogeneities.

The discussion then moved on to the topic of galactic evolution. It was argued that galaxies evidently originate from a single protogalactic cloud, since the globular clusters display a range of properties that vary systematically through the Galaxy, and from one galaxy to another (S. van den Bergh, University of Toronto). But this "monolithic" unit may have increased in size as a result of infalling material, as suggested by measurements of stellar metallicities in the solar neighbourhood (D. Lynden-Bell, IOA, Cambridge). Direct calculation of the collapse of a turbulent protogalactic cloud led to fragmentation into $10^{5-7} M_{\odot}$ clouds, with the formation of a massive central star in each cloud fragment, inhibiting further star formation (B. Jones, and S. Weber, University of California, Berkeley). It is not clear how further evolution would proceed from this point. At any rate, the two theories of galactic evolution presented at the workshop each included an assumed star formation rate without regard to the detailed physical processes involved. The first model by Gott and T. X. Thuan (CalTech) took as its starting point a rotating protogalactic cloud, and assumed that star formation occurred over some characteristic timescale, T_{st} . If this were short compared with the collapse timescale of the galaxy, T_{tr} , then the result was an elliptical system, and if long ($T_{st} > T_{tr}$) it formed a disk system. The second model (R. Larson, Yale University) began with a turbulent protogalactic gas cloud, in which star formation took

place at an assigned rate during collapse. If the cloud had low angular momentum an elliptical system was formed, and if high angular momentum, a disk system formed, though some additional adjustment of other parameters was required in the latter case.

Neither model is perfect. Evidently, elliptical systems are easier to make than spiral ones, though even here there were some notable discrepancies.

Gott's model being dissipationless produced a majority of EO systems though it had the nice property that the maximum flatness produced was E7 (Gott and Thuan). Observations suggest however that E3 is the most common type. Conversely Larson's model tended to produce too much flattening. In each case, flattening was said to have derived from rotation.

But both models gave the observed luminosity profile for elliptical galaxies, assuming a constant mass to light ratio. Various studies suggest, however, that the mass to light ratio may vary; it is early days yet for the galaxy builders.

The situation as regards the formation of spiral galaxies is even less satisfactory. There seems to be some difficulty in producing a clear division of type between ellipticals and spirals when starting with the same initial conditions and continuously varying parameters. Van den Bergh pointed out that SOs were not truly intermediate in type between the two classes, their ellipticity and luminosity profiles both being characteristic of spirals. He emphasised the value of the bulge/disk ratio as an indicator of spiral type and it was even suggested (Ostriker and Faber) that all galaxies could be classified by means of their elliptical component, going from large ellipticals, through spirals, to dwarf elliptical systems. But the mechanism by which the disk is produced is not clear.

Faber suggested that the bulge/disk ratio may be a factor in the removal of gas, arguing for the presence of a galactic wind in spheroidal systems; however, van den Bergh pointed out that this could not be the only factor involved in gas loss, since ellipticals and SOs are predominantly found in clusters. He therefore supported the idea that gas is stripped from galaxies by the ram pressure of an intergalactic gas. This process was proposed by G. R. Gisler (IOA, Cambridge) to explain the very low gas content found in most elliptical systems, where population synthesis studies indicate that more gas is being lost by stars than is evidently consumed by new star formation (B. Tinsley, Yale University, and W. O'Connell, University of Virginia). This assumes a normal stellar mass function, since there is no obvious way to manufacture only low mass stars.

But since the ram pressure effect could not easily account for the variations in gas content in spiral systems it seems likely that more than one process is operating to influence the gas content of galaxies in general.

The last problem to be considered was the possible detection of galaxies in the process of formation. An argument based on free-fall times suggested that galaxies would have formed between a redshift of 50 and 5, and perhaps as recently as $z=3$ (Larson). An elegant study by D. Meier (University of Texas, Austin) based on the models of Larson and Tinsley, predicted a possible spectrum for a newly formed galaxy, and indicated that its nucleus could be visible as a QSO. He proposed two candidate objects worthy of further investigation in this field: OH471 and 4C0534. The principal argument against Meier's work is that it neglects the effect of dust. This is a significant omission, since if most of the radiation were absorbed by dust and re-emitted in the infrared, it may be difficult or impossible to detect (M. Rowan-Robinson, Queen Mary College, London). But what is particularly unfortunate for those engaged in the task of galaxy making is that there are apparently no reasonable candidates for galaxies in the process of formation now (W. L. W. Sargent, CalTech). Presumably, this implies that either there are no more suitable protogalactic clouds around, or that conditions are no longer right for turning them into galaxies, or both. In the words of Sidney van den Bergh: "Galaxies are like people: they depend on both genetics and environment". This, indeed, was the theme of the workshop. □

A hundred years ago

A UNIVERSITY is to be founded at Tomsk, one of the chief towns of Siberia. The new establishment will have only two faculties, one of Law and the other of Medicine. The want of doctors in Siberia may be inferred from the fact that there are only fifty-five of them in a country which is as large as the whole of Europe, and whose population amounts to more than 6,000,000 inhabitants. The Russian Minister of Finance has granted a credit of 40,000*l.* on the revenue of the State for the new establishment, which will raise the number of Russian Universities to eight.

Unified gauge theories of elementary particles

E. Leader & P. G. Williams*

Recent theories which unite weak and electromagnetic interactions provide new hope for a unified theory of fields and their interactions. Experimental developments such as the discovery of neutral currents and the new psi particles lend encouraging support for some of the ideas embodied in these theories.

One of the principal goals of 20th century physics has been to obtain a unified understanding of all the basic interactions observed in nature. Einstein spent his later years attempting to unify electromagnetic and gravitational interactions. His failure, and that of some of his contemporaries, was one of the reasons why the pursuit of such grand theoretical syntheses lost its popularity. Instead the main effort of fundamental physics has been concentrated on less ambitious, more limited goals, studying each interaction more or less in isolation.

In the past three years unification has once more come into vogue through some quite remarkable theoretical and experimental developments in high energy physics. In this article we shall attempt to outline the ideas behind these developments.

The past 40 years have led to the elucidation of four distinct types of forces or interactions acting between elementary particles: the strong, the electromagnetic, the weak and the gravitational forces, with relative strengths in the ratios $1 : 1/137 : 10^{-13} : 10^{-39}$. Whereas gravity acts upon all particles the other forces seem to be more selective. Table 1 lists a few of the known elementary particles and the forces they experience.

When hadrons interact it is difficult to study their weak and electromagnetic properties since their strong interactions are predominant. We cannot switch off the strong interactions; but nature has provided its own probe—the leptons—which seem to have no strong interactions. For the moment we shall confine our attention to the leptons, returning to hadron physics again later.

Electromagnetic interaction of leptons

A typical leptonic electromagnetic process is the scattering of one electron by another: $e^- + e^- \rightarrow e^- + e^-$. Classically the two negatively charged electrons repel each other and are deflected from their original paths.

In quantum field theory the interaction is pictured as arising from the exchange of an electromagnetic wave (that is a photon) between the two electrons as in (1).

But this is not the only mechanism contributing to the scattering: two or more, in fact any number of photons can be

exchanged. The physical process is described by the sum total of all such mechanisms (2).

Each of these "Feynman" diagrams corresponds to a precise mathematical expression. Each photon exchanged represents one interaction with the electromagnetic forces. Fortunately these forces are so weak that the more photons there are in a diagram the smaller its contribution. The force produced by the exchange of a single photon depends on the strength of the "coupling" between the photon and the electron. This is equal to the electric charge, e , of the electron. In Fig. 1 the force is proportional to $e^2 = 1/137$. Thus the scattering process is described by a series of successively decreasing terms proportional to e^2 , e^4 , e^6 , and so on. Unfortunately some diagrams give rise to mathematical expressions which when evaluated are infinitely large. An example occurs at order e^4 where each of the three diagrams in (3) is infinite—but miraculously their sum is finite! Crucial to this cancellation of infinities is

the "universality" of the coupling of the photon to electrically charged matter: the fact that the force is always proportional to the electric charge, and is always the same; the electric charge is "conserved". Quantum electrodynamics is riddled with these infinities, but they always cancel. A field theory with this remarkable property is said to be "renormalisable".

It is sometimes said that the finiteness of the theory depends on the fact that the photon has zero mass; but this is not the case. One can imagine a theory of electrodynamics with massive photons and this is also renormalisable. That the mass of the photon is zero is an experimental fact intimately connected with the inverse square law, and known to great accuracy. A consequence of the zero mass of the photon is that electromagnetic waves are transverse, having only two possible polarisation states, both perpendicular to the direction of propagation.

* Address: Westfield College, University of London, London, UK.

Table 1 Properties and interactions of some elementary particles. Superscripts denote the electric charge in units of the electronic charge e : thus μ^+ has charge $+e$; μ^- charge $-e$

Generic name	Interactions	Particles	Antiparticles
Hadrons	Strong Electromagnetic and Weak	Proton p	Antiproton \bar{p}
		Neutron n	Antineutron \bar{n}
		Pions π^+	π^-
		π^0	π^0
Strange particles		Kaons K^+	K^-
		K^0	\bar{K}^0
		Lambda Λ^0	Antilambda $\bar{\Lambda}^0$
Leptons	Weak and electromagnetic	Electron e^-	Positron e^+
		Muon μ^-	Antimuon μ^+
	Weak	Electron	Electron
		Neutrino ν_e	Antineutrino $\bar{\nu}_e$
		Muon	Muon
		Neutrino ν_μ	Antineutrino $\bar{\nu}_\mu$

A massive "photon" could also have a longitudinal polarisation and therefore a total of three polarisation states. These states of longitudinal polarisation are additional sources of infinities when the "photon" has a mass, but they cancel as a result of charge conservation. That is why the electrodynamics of massive "photons" is also renormalisable.

To summarise: the quantum electrodynamics of electrons and photons is a complete theory in the sense that all physical processes involving only electrons and photons can be calculated to arbitrary accuracy by perturbation theory, and the results are finite. The experimental record of quantum electrodynamics is impeccable: there are no known deviations from the theory and some predictions agree with experiments to within parts per million.

We have remarked that the cancellation of infinities in quantum electrodynamics is miraculous. In the next section we shall examine the mechanism behind this miracle.

Gauge invariance

To every conservation law in physics there corresponds a symmetry of the dynamical laws. For example, energy and momentum conservation are consequences of the symmetry of physical laws under translations in time and space: angular momentum conservation is a result of symmetry under rotations.

Charge conservation, the root cause of the renormalisability of quantum electrodynamics, is connected with the fact that the electromagnetic potentials are not unique, but may be altered in a particular way at different points in space and time without any change in the form of the laws of electrodynamics. In a quantum field theory these changes in the electromagnetic potentials are always accompanied by a change in the fields that represent the particles; the particles react to the effect of the change in the electromagnetic potentials, but in just such a way as to leave the physics unaltered. This symmetry is termed gauge invariance. To emphasise that each point in space-time has its own different gauge transformation we use the nomenclature "local" gauge invariance.

Not only does local gauge invariance lead to charge conservation, but it also forces the photon mass to be zero. But as we mentioned before massive photons also give a renormalisable electrodynamics, so that local gauge invariance is a larger symmetry than needed for charge conservation and for renormalisability. It turns out that all we require for charge conservation is a "global" gauge invariance where the gauge transformations are the same at all space-time points. The photon may have a mass without violating this symmetry.

This approach to charge conservation may seem rather formal, but it lends itself to generalisations that will lead to a theory for the weak interactions.

Weak interactions

At first sight it might seem that weak interactions have no features in common with electromagnetic processes. The β decay of the neutron into a proton, electron and antineutrino ($n \rightarrow p + e^- + \bar{\nu}_e$), the decay of muons $\mu^- \rightarrow e^- + \bar{\nu}_e + \nu_\mu$, are very different from typical electromagnetic interactions. Besides being far weaker, they violate parity conservation (that is left-right symmetry) and involve very short range forces; electromagnetic forces conserve parity and are long range as a result of the zero mass of photons. Yet Fermi, who first wrote down a theory of weak interactions in a remarkable paper in 1934, based his ideas on a close analogy with electrodynamics.

Let us imagine doing an experiment analogous to electron-electron scattering considered earlier, but involving only weak interactions. A good example involving only leptons is the elastic scattering of neutrinos off electrons, $\nu_e + e^- \rightarrow \nu_e + e^-$. By analogy with electrodynamics we shall assume that the weak force responsible for this scattering process is caused by the exchange of some "weak photon" called the W meson or W boson, as shown in (4). Note from the figure that since the neutrino has no electric charge, the W boson must have the same charge as the electron. As will be discussed later, until

recently all experiments suggested that only charged W boson exchange occurred. If there were a neutral W boson, we could have also drawn a second diagram (5).

The first diagram (4) is called a "charged current" interaction; the second (5) a "neutral current" interaction. The latter bears the closest relation to electromagnetism because the photon also has no charge.

Now it can be shown that the range of the force generated by the exchange of a particle is inversely proportional to its mass. Experiment shows that the weak interactions are so short ranged that the W boson mass must be greater than that of any known particle. (Fermi's original theory corresponds to an infinite mass W.) Our failure so far to observe any W bosons could well be because our accelerators are not energetic enough to create them in the laboratory. Their discovery would constitute by far the most decisive evidence in favour of the picture we have painted of weak interactions.

The theory outlined above—both in Fermi's original form and with a sufficiently large W mass—has been most successful in correlating the various phenomena of weak interactions. But it only works in the lowest order of perturbation theory. In our example of neutrino-electron scattering, the next most complicated term to be added to (4) is shown in (6) and is infinite.

(6)

Unlike quantum electrodynamics there is no way of cancelling the infinities of the theory—it is non-renormalisable. The trouble lies in a failure to pursue the analogue with electrodynamics closely enough: the theory contains a "weak photon" (the W boson) but there is no "weak charge" conservation, and the experience of quantum electrodynamics suggests that this is the ingredient needed to obtain a renormalisable theory. This problem was solved by Yang and Mills in 1954.

Yang-Mills gauge theories

The difficulty of constructing a gauge invariant theory of the W bosons is that unlike the photon they must have electric charge. The photon, which only interacts directly with charged particles will not interact directly with itself. But Yang and Mills showed that because W bosons are charged they must interact with themselves and to achieve a gauge invariant theory one must also have a neutral W^0 in addition to W^+ and W^- . The possible diagrams are much more complicated now because three or four Ws can interact with each other as shown in (7).

(7)

These Yang-Mills theories are a natural extension of electrodynamics, because they possess the full local or space-time dependent gauge invariance only when the W bosons are massless, but the introduction of masses still preserves the conservation of a "charge". This is, of course, not the electric charge but something we shall wish to identify as the weak charge alluded to in the previous section. We have already mentioned that electrodynamics with massive photons is renormalisable because charge conservation is sufficient to guarantee this without need for the full local gauge invariance.

Weak interactions are short range and therefore require massive W bosons. The analogy with electrodynamics with massive photons suggests that a massive Yang-Mills theory will be renormalisable and, therefore, could provide the basis for a theory of weak interactions.

At first it might seem that massive Yang-Mills theories are indeed renormalisable. Thus, in the example of elastic neutrino-electron scattering the introduction of a self-interacting W boson leads to the addition of further diagrams to the infinite two W boson exchange diagram (8).

(8)

All these diagrams are individually infinite, but their sum is finite—the infinities cancel out exactly. Unfortunately it was later shown that such cancellations do not always occur and therefore massive Yang-Mills theories are not, in fact, renormalisable. It turns out that the full local gauge invariance is a necessary requirement and this means that the W bosons cannot be given a mass, although experiment requires it.

The inescapable conclusion seemed to be that gauge theories, except in the simplest case, electrodynamics, do not apply to the real world. In 1971, however, a Dutch graduate student, 't Hooft, opened the flood-gates by giving convincing arguments for the renormalisability of a rather special type of Yang-Mills gauge theory. Such theories circumvent the difficulties described in this section by an ingenious and elegant device.

Secret symmetries and Goldstone bosons

To describe the developments that led to the salvation of gauge theories we must digress to consider the concept of a "secret symmetry", sometimes confusingly called a "spontaneously broken symmetry". This idea concerns physical systems displaying properties which seem to violate the symmetry possessed by the underlying physical laws. The best example of a secret symmetry is a permanent bar magnet. The interactions between the atoms and molecules are certainly invariant under rotations yet the bar magnet is magnetised in one particular direction. The magnet is not invariant under rotations, because the direction of magnetisation is singled out as a special one, but the underlying physical laws are. What application does this have to high energy physics? Perhaps the W bosons having a non-zero mass are like the bar magnet. Perhaps the underlying physical laws are invariant under local gauge transformations, despite the non-zero mass of the W's.

In 1961, Goldstone pointed out that any system having a secret symmetry pays a price for its secrecy: there must exist zero frequency modes or, in the case of relativistic field theory, there must exist spinless zero mass particles. These particles are called Goldstone bosons. In the ferromagnet, Goldstone bosons correspond to spin waves propagating through the solid. This would seem to spell the end of hopes for using secret symmetries in gauge theories because no zero mass Goldstone bosons have ever been observed in high energy physics experiments.

In 1964, Higgs, and independently Brout and Englert made a discovery, the true significance of which has only recently been fully appreciated. The Goldstone theorem has buried in it the assumption that there must be no long range forces; otherwise the chain of reasoning leading to zero mass Goldstone bosons breaks down. Of course, zero mass vector mesons such as the photon and the W bosons of Yang-Mills gauge theories do produce long range forces and so these theories avoid the strictures of Goldstone's theorem—Goldstone bosons need not exist.

Higgs showed that not only do zero mass Goldstone bosons not need to occur, but that a gauge theory with secret symmetry

can be made to use a spinless particle—now called the Higgs meson—to give the W bosons a mass. The freedom supplied by gauge invariance enables us to 'mix-up' the Higgs meson with a third polarisation state of the W bosons. In other words, the zero mass gauge particles which possess two states of polarisation, and the Higgs meson, which possesses one state of polarisation, combine to produce massive Ws with three states of polarisation, and the Higgs meson as an independent particle disappears. In the process the gauge symmetry seems to have been lost, but it is still there only rather well hidden. Although this fact was understood at the time, it was felt that since the symmetry is so well and truly hidden by the Higgs mechanism, there was no reason for the theory to be renormalisable.

Unified gauge theories

In 1967 two short papers appeared in which the electromagnetic and weak interactions of leptons were unified in a gauge theory using the Higgs mechanism. One by Weinberg suggested that the theory might be renormalisable; the other by Salam argued that since the underlying theory has a gauge symmetry, perhaps the Higgs mechanism does not spoil its renormalisability.

The Salam–Weinberg theory barely caused a flutter until 1971 when 't Hooft gave his non-rigorous but convincing arguments that theories of this type are indeed renormalisable. 't Hooft's work caused a considerable stir because it then became possible for a gauge theory to apply to weak interactions. Since an essential ingredient in a wide class of gauge theories is the existence of an electrically neutral W boson, extensive experimental work was initiated, not to find it directly, but to see its effects as an exchanged particle producing a weak force—as a neutral current.

Before we discuss the experimental evidence for neutral currents let us briefly describe the main features of the Salam–Weinberg theory. First we should stress that the theory originally concerned only the weak and electromagnetic interactions of leptons, the electron e^- and its neutrino ν_e , the muon μ^- and its neutrino ν_μ . The Salam–Weinberg theory is a gauge theory with a total of four gauge vector mesons all starting out with zero mass; but the Higgs mesons in the theory are carefully chosen to give a mass to only three of the bosons when the symmetry becomes a secret one. These are the W^+ , W^- and W^0 of the weak interactions. The fourth gauge boson remains massless and is identified with the photon. The combined existence of all four of these particles is a necessary part of the gauge symmetry itself and therefore of the renormalisability. There are ways of avoiding a neutral W boson; but the price to be paid is heavy: the number of leptons must be increased by the introduction of heavy leptons.

In what sense does such a gauge theory represent a unification of electromagnetic and weak interactions? This comes about through the special status that the gauge particles have in a gauge theory—they all couple to matter and to each other with the same universal coupling strength $e^2 \approx 1/137$. But whereas the exchange of zero mass particles (photons) produces an effective coupling e^2 typical of electromagnetic interactions, the exchange of W bosons of mass M_w turns out to have an effective coupling e^2/M_w^2 . For this to be as small as the observed weak interaction strength requires a very large mass M_w of at least 40 GeV, or 40 times the mass of the proton! This rather general property of unified gauge theories makes it unlikely that W bosons will be produced directly in experiments in the near future. Instead experiments have concentrated on the search for neutral current effects in neutrino scattering processes.

Evidence for leptonic neutral currents

Until recently neutrino physics has been something of a poor relation in high energy physics. It is difficult to produce intense neutrino beams, and interactions are so rare that experiments take a long time to perform. In the past few years, however, with the prospect of new high energy accelerators, much effort

has been invested in new equipment, just in time to make an effective search for neutral currents.

There are only two basic processes involving leptons able to provide experimental tests for the existence of neutral currents: the scattering of either electron or muon neutrinos and anti-neutrinos off electrons. Both reactions occur at very low rates and are therefore very difficult to measure, even by the standards of neutrino physics. The first (9) would occur even in the absence of neutral currents, but the second (10) is a pure neutral current process that would be absent if only charged currents occur.

(9)

(10)

It is essential to note that (10) represents the only independent one W boson exchange diagram contributing to $\nu_\mu + e^- \rightarrow \nu_\mu + e^-$ because experiments have shown that muons and their neutrinos cannot turn into electrons and their neutrinos. These "lepton number" conservation laws are an important ingredient in the interpretation of neutral current experiments. Thus diagram (11) which would be the analogue of the first diagram in (10), is forbidden by the conservation of lepton number.

(11)

The muon neutrino experiment is the most decisive one, and was carried out at CERN using a large bubble chamber facility specifically designed for neutrino experiments. The first results were announced in 1973, showing one event believed to be $\bar{\nu}_\mu + e^- \rightarrow \bar{\nu}_\mu + e^-$. This experiment has continued to accumulate statistics, and at present the total number of neutral current events is three. It is impossible to exaggerate the difficulty of such an enterprise. Everything hinges on being certain that what is observed is not some other process. The problem is that the only observed product of the collision process is the final electron coming out of the reaction. Neither the incoming nor the outgoing neutrinos can be observed, and the electron might well result from processes involving other unobserved neutral particles such as neutrons or photons. Much of the effort and nearly all the discussion revolves around the estimation of the background events. In this experiment they have been estimated to be around 10%, but with only three events at hand who can be certain?

Potentially this experiment is the best test of the Salam–Weinberg gauge theory; but the most reliable evidence for neutral currents has come from neutrinos scattering off hadrons where the event rates are considerably higher. Now, however, the

strong interactions enter into the picture, to obscure and complicate the theoretical interpretation. We must consider the possible ways of extending unified gauge theories to hadrons.

Hadrons and quarks

Up to now we have been discussing the leptonic world consisting of the electron, muon and their neutrinos. As far as we know the forces between these particles are only weak and electromagnetic. Indeed, the neutrinos, being neutral, do not even have electromagnetic interactions. This is why they are able to penetrate enormous quantities of material, such as stars and the Earth itself.

Besides the leptons there is a vast array of particles including protons, neutrons, nuclei, π mesons, K mesons, strange particles and many other so-called "elementary" particles all of which have strong or nuclear interactions. These hadrons have interactions amongst themselves some 100 times stronger than the electromagnetic interactions and some 10^{13} times stronger than the weak interactions. The structure and behaviour of hadrons is almost entirely determined by the strong interactions. Hadrons, however, also have electromagnetic and weak interactions, although these are heavily influenced by the strong interactions. An example of a hadronic weak interaction is β -decay of the neutron: $n \rightarrow p e^- \bar{\nu}_e$. How can we picture this interaction as the exchange of an intermediate vector boson? The answer, already implicit in Fermi's original theory of 1934 is that the neutron emits a charged vector boson which then decays into the leptons.

The coupling of the W boson to hadrons, however, is not as simple as it is to the leptons, because it is influenced by the strong interactions. The latter determine the structure and constitution of the hadrons, which it has become vogue to describe in terms of hypothetical fundamental constituents, the "quarks". In the quark model the hadrons are all built out of three quarks q_p, q_n, q_λ and their antiparticles $\bar{q}_p, \bar{q}_n, \bar{q}_\lambda$. This leads in a simple way to the famous SU(3) classification of particles. For our present purposes all we need note is that mesons such as the π or K are presumed to be bound states of a quark and antiquark, whereas baryons such as protons and neutrons are bound states of three quarks. Quarks have never been produced in experiments, but the remarkable success of the quark model is taken as evidence that it contains at least some element of truth.

The quark model simplifies the problem of weak decays of hadrons by enabling us to express them all in terms of the decays of only the quarks themselves. A simple example is the decay $\pi^- \rightarrow \pi^0 + e^- + \bar{\nu}_e$ now depicted as in (13), where the quarks are assumed to have simple weak and electromagnetic interactions like the leptons. The complications of the strong interactions are then hidden in the fashion in which the hadrons are built up from the quarks.

The simple symmetry properties of quarks enable them to be included in a natural elegant way in a unified gauge theory of weak, electromagnetic and possibly even strong interactions. Nearly all such theories have neutral W bosons as an essential ingredient, so that once again their exchange as neutral currents provides the best available experimental test. We shall see later that the possible existence of a new quantum number "charm" may provide even more decisive evidence in favour of unified gauge theories.

Tests for neutral hadronic currents

We have already emphasised the problematic nature of hadronic interactions; but from the point of view of gauge theories our catalogue of difficulties is by no means complete. For some years there has been powerful evidence against the existence of neutral currents in "strangeness changing" weak processes. These are processes where the initial and final hadrons have different values of the strangeness quantum number. A classic example is the strangeness changing decay $K^+ \rightarrow \pi^0 + e^+ + \nu_e$ which has been observed experimentally and which involves a charged current; but the very closely related decay $K^+ \rightarrow \pi^+ + e^+ + \nu_e$ which would involve a neutral current is suppressed by a factor of about a million.

An even more important example of a strangeness changing decay process is that of the long lived neutral K meson. This process $K_L^0 \rightarrow \mu^+ + \mu^-$ involving a neutral current is 10 million times less frequent than the similar but charged current decay $K^+ \rightarrow \mu^+ + \nu_\mu$. This suppression is so strong that not only must the lowest order diagram in (14) vanish, but the second order diagram in (15) also must be suppressed.

Before the advent of unified gauge theories it was assumed that this type of suppression occurred for all weak processes, whether or not there is a change of strangeness, and that neutral currents simply did not occur. Only with the renaissance of gauge theories resulting from belief in their renormalisability was it felt necessary to perform the difficult experiments required to check this suppression in hadronic processes not involving changes of strangeness. The first evidence was found in the summer of 1973 at CERN. Since that time further experiments both at CERN and in the USA have confirmed the existence of neutral currents that do not change strangeness. A typical event observed at CERN is $\nu_\mu + n \rightarrow \nu_\mu + p + \pi^- + \pi^0$. Since no strange hadrons are involved in the reaction there is no change of strangeness, but as (16) shows, there is a neutral W boson exchanged.

Other successful experiments have been performed which together provide conclusive evidence that neutral currents exist which do not change strangeness; but strangeness changing currents either do not exist or, if they do, are highly suppressed. What mechanism is responsible for this sharp distinction? The most elegant solution has been proposed by Glashow, Iliopoulos and Maiani.

Charm

Whenever there is a strong suppression of some otherwise innocuous process there is a good chance that a symmetry or conservation law is responsible. One way to get rid of neutral currents that change strangeness is to invoke greater symmetry so as to arrange for a universal cancellation of the unwanted processes. New symmetry means new conserved quantum numbers and new particles to carry these quantum numbers. The new quantum number invoked is "charm" and has analogous properties to those of strangeness. Just as we already have a strange quark q_s , we now need a fourth "charmed" quark q_c . It must be incorporated into a gauge theory in such a way as to preserve the gauge symmetry and therefore the vital renormalisability of the theory. In this way the unwanted process $K^+ \rightarrow \pi^+ + e^+ + e^-$ is made impossible. The unwanted $K_L^0 \rightarrow \mu^+ \mu^-$ process is, however, more subtle. The most direct way of picturing the decay shown in (14) does indeed vanish because now the W^0 cannot couple to a q_s and turn it into a q_s . But the second order diagram in Fig. 15 is still not zero.

There is now, however, an additional similar diagram involving a charmed quark in (17),

Note presence of charmed quark

which exactly cancels the diagram in (15) because of the close connection between the couplings: due to the gauge symmetry the coupling of the charmed quark q_c to W^+ and W^- is just the opposite to the proton quark q_p .

If this explanation of the absence of strangeness changing neutral currents is to be anything more than a theoretical exercise it must lead to other consequences open to experimental test. The merit of the charm theory is that it has many distinctive predictions. It invokes a new quantum number and therefore new particles carrying charm. In August 1974 M. K. Gaillard, B. W. Lee and J. L. Rosner showed how the existence of the charm quantum number would lead to an extension of the well known $SU(3)$ classification scheme to $SU(4)$ where the now familiar octets become groups of 15 or more particles. Most of the new particles have charm, but some do not. In particular the ϕ meson, a known and rather peculiar vector meson of mass 1.02 GeV or 1.08 times that of the proton, gains a partner, the ϕ_c whose estimated mass is about 2-3 GeV.

The new particles

In what sense is the well known ϕ meson peculiar? It has an unexpectedly long lifetime some twenty times greater than other unstable hadrons. Indeed, the strong decay into three light π mesons, $\phi \rightarrow \pi^+ + \pi^- + \pi^0$ which was expected to be its major decay mode is some $4\frac{1}{2}$ times less frequent than the decay into two heavy K mesons, $\phi \rightarrow K + \bar{K}$. The conventional explanation for the unusually long lifetime of the ϕ meson is based on the quark model. Although in principle ϕ can consist of any mixture of $q_s \bar{q}_s$, $q_p \bar{q}_p$ and $q_n \bar{q}_n$ quarks, in fact it is almost entirely made up of the strange quarks $q_s \bar{q}_s$. Pions are made up of protons and neutron quarks only, so that the ϕ meson finds it hard to turn into pions; but since ϕ is predominantly made of

strange quarks it has no difficulty manufacturing K mesons since these also contain strange quarks. The only problem for the ϕ is that the K mesons are so heavy that there is only just enough energy available to form two Ks. Thus the ϕ meson is long lived for two reasons: it is mainly composed of strange quarks, and strange K mesons are much heavier than non-strange π mesons.

The ϕ_c is a companion to the ϕ in the sense that it is expected to be mainly made of charmed quarks $q_c \bar{q}_c$ just as the ϕ is mainly composed of strange quarks. But the interesting possibility noted by Gaillard, Lee and Rosner was that the analogues of the strange K mesons, the charmed D mesons might be too heavy to be possible decay products of the ϕ_c . Thus the ϕ_c would find it difficult to decay at all and its lifetime might be even longer than that of the ϕ .

History would doubtless have consigned charm and all papers about charmed particles to that voluminous file entitled "unsuccessful higher symmetry schemes", had it not been for the discovery in November 1974 of a particle of mass 3.1 GeV and a lifetime 40 times longer than that of the ϕ ! This particle, currently named ψ , was seen both in hadron collision, at Brookhaven and in electron-positron collisions at the intersecting storage rings SPEAR in Stanford. It has been identified as a vector meson with many of the characteristics expected of the ϕ_c . But whether it is indeed the ϕ_c awaits further experimental work. Particularly interesting is the question of the existence of particles with charm, such as the D mesons. A slightly heavier long lived particle the ψ' , having a mass of 3.7 GeV was discovered soon after the ψ . The relationship between the ψ and the ψ' is playing an important part in elucidating the true nature of these new particles, as is the discovery in the same experiments of a much shorter lived particle of mass 4.1 GeV, the ψ'' . This proliferation of new particles has caused a great deal of excitement and activity. Speculations, explanations, confirmations, further facts and even candidates for charmed particles appear weekly. Sometimes the omens are good for charm: the ψ is the ϕ_c ; sometimes there is alarm as expected features are not found. At the moment of writing there are worries because no charmed decay products of the ψ'' have been seen; but until the dust settles there is no definite conclusion one can draw except that charm is still perhaps the most favoured explanation. The decisive test for charm is undoubtedly the observation of charmed particles such as the D mesons.

Unified theory of strong interactions?

At this point we have, in principle at least, a unified gauge theory of the electromagnetic and weak interactions of all elementary particles. Can we now take the ultimate step of including also the strong interactions? The problem with theories of strong interactions is that one cannot calculate their consequences accurately, since perturbation methods do not work, and so one can never test the starting hypotheses in detail.

Recently, however, there has been an important theoretical development using so called "renormalisation group" techniques, which has proved of value in the theory of phase transitions in solid state physics, and which may be of help in solving problems involving strong interactions. It has been possible to demonstrate that some types of interaction develop simpler and simpler properties as the energy increases, leading ultimately to a behaviour somewhat like that of non-interacting or free particles! Such theories are called "asymptotically free field theories", and it is possible within them to do some calculations based on perturbation methods.

Until the advent of unified gauge theories there were no known examples of asymptotically free field theories. What is quite remarkable is the discovery that a wide class of gauge theories possess this property. It may, therefore, be possible to incorporate the strong interactions into what would then be a truly unified gauge theory, and to make detailed predictions

which could then be tested experimentally. Much effort will no doubt be expended on this challenge in the next few years.

The present state of theory

We have now followed the development of gauge theories to the present day. Starting from the successful theory of quantum electrodynamics we have traced its extension into the realm of weak interactions. This led to Yang-Mills gauge theories with massive W bosons. The theories are renormalisable only because they possess an underlying symmetry which has been hidden but not destroyed by the Higgs mechanism. The most accessible experimental consequence of these theoretical ideas is the existence of neutral currents induced by neutral W boson exchange, and these have been detected in neutrino experiments. The most direct evidence for unified gauge theories would be the discovery of the W^+ , W^- and W^0 mesons; but their large predicted masses makes this an unlikely possibility for the foreseeable future. This large mass is the price paid for unifying weak and electromagnetic interactions.

The extension of these ideas to the weak and electromagnetic interactions of hadrons produced an immediate conflict with the

experimental fact that strangeness changing hadron decay processes such as $K_L^0 \rightarrow \mu^+ + \mu^-$ are highly suppressed. To achieve such suppression a new quantum number, charm, has been invoked, leading to a rich harvest of experimental predictions. The new ψ particles may indeed be indirect manifestations of this quantum number, but the final acceptance of the idea of charm depends on the success or failure of the experimental search for D mesons and other charmed particles.

The theory invoking charm is by no means unique, and failure to observe charmed particles will lead to its rapid demise. Success on the other hand will enable us to take a large step forward, providing circumstantial evidence in one fell swoop for a wide range of theoretical ideas. The stage may then be set for a grand unification of weak, electromagnetic and strong interactions. Whatever the ultimate fate of the theoretical ideas presented in this brief survey, there is no doubt that they have stimulated a remarkable series of experimental and theoretical developments. There is surely no more apposite comment than that of Einstein and Infeld some 50 years ago:

"To raise new questions, new possibilities, to regard old problems from a new angle, requires creative imagination and marks a real advance in science."

Structure of the compact radio component in 3C236

E. B. Fomalount

National Radio Astronomy Observatory, Green Bank, West Virginia

G. K. Miley

Sterrewacht, Huygens Laboratorium, Leiden, The Netherlands

The compact component in the giant radio galaxy 3C236 has been studied at 0.4, 2.7 and 8.1 GHz, with resolution of up to 0.13". The overall structure is double and asymmetric. The extent is 0.8" in a position angle of $121 \pm 4^\circ$ which, within the uncertainties, is the same as that of the large outer 39' double. No difference between the spectra of the subcomponents was detected. On a scale of 0.2" there is fine structure. The radio subcomponents are almost certainly not confined and are thus the results of a relatively recent event in the nucleus of 3C236. Our results are compatible with continuous flow models which are well collimated along an axis whose alignment does not change significantly during the lifetime of the source.

SMALL radio components with relatively flat spectra are now known to occur in the nuclei of many radio galaxies and QSOs. They almost certainly have an important role in producing and maintaining the extended double radio structure and their study is crucial to any understanding of the physical processes involved.

One of the most interesting examples of a double radio source with a compact central component is the giant radio galaxy 3C236. It is the only case where the radio core is sufficiently extended that its structure can be studied in detail. In 1972 Wilkinson^{1,2}, using the radio link interferometer at

Jodrell Bank, showed that the nuclear component of 3C236 (then believed to comprise the whole source) is extended by $\sim 1''$ in position angle (p.a.) 119° . Willis *et al.*³ showed that 3C236 has an overall extent of about 39' (~ 5.7 Mpc)⁴ in p.a. 122.5° . (Throughout this article a value of $50 \text{ km s}^{-1} \text{ Mpc}^{-1}$ is assumed for the Hubble Constant, implying a distance of 554 Mpc to 3C236.) The remarkable alignment of the $1''$ compact component with the 39' outer double has important implications for radio source models and deserves further investigation. We present here the results of a detailed study of the structure of the compact component of 3C236 at frequencies of 0.408, 2.695 and 8.085 GHz using several interferometer baselines out to a length of 950,000 wavelengths.

Observations

The 2.695 and 8.085 GHz observations were carried out with the NRAO four-element interferometer. This array consists of three steerable 85-foot antennae with a maximum baseline length of 2.7 km, and a 45-foot antenna located about 35 km south-west of the other elements. The 45-foot antenna is connected to the control building using a phase-stable radio link⁴ and three baselines of 33.1, 33.9 and 35.3 km are obtained by correlating the signals of the 45-foot element with each 85-foot antenna. The original three-element system has been described by Hogg *et al.*⁵ and Coe⁶. The noise after 15 min of observations corresponds to ~ 0.03 Jy at 2.695 GHz and ~ 0.05 Jy at 8.085 GHz. The source was observed on December 26 and 28, 1974, between sidereal times 04 h 30 min and

Fig. 1 The range of projected baselines used in this study. u is the east-west and v the north-south baseline in millions of wavelengths. u is measured to the left. The line denoted by M_0 indicates the amplitude maximum that would be observed from a source elongated in p.a. 122.5° (same as that of the overall $39'$ structure). M_1 , M_2 , M_3 and M_4 indicate observed fringe amplitude maxima and m_1 , m_2 and m_3 observed minima (see Fig. 2).

15 h 20 min. To calibrate the phase and gain drift, we alternated observations every 10 min between 3C236 and DA267, a nearby calibrator. The redundancy in the two days of observations helped us to estimate the residual phase and gain errors in the calibrated data. The baseline parameters of the array were obtained to an accuracy of $0.02''$ from subsequent observations of sources with accurately known positions (C. M. Wade and K. Johnson, unpublished). The visibility amplitude and phase of 3C236 were measured with respect to DA267 with an assumed position (epoch 1950.0) of $\alpha = 09^h 23^m 55.320^s$, $\delta = 39^\circ 15' 23.55''$ and assumed flux density (epoch 1975.0) of $S_{2695} = 4.5$ Jy and $S_{8085} = 9.7$ Jy (L. Blankenship, unpublished). The residual phase and gain errors were $\pm 10^\circ$ and $\pm 10\%$ at 2,695 MHz and $\pm 30^\circ$ and $\pm 20\%$ at 8,085 MHz and their effect was generally larger than that of the receiver noise.

The 0.408 GHz observations were made with a single baseline interferometer of length 122 km whose elements were the Mark Ia telescope at Jodrell Bank and one of the 25-m paraboloids at the Royal Radar Establishment, Defford. The system was basically similar to that described by Rowson⁷ with the addition of a digital delay line designed by B. Anderson. Here only fringe amplitudes were measured and no useful information was available about the absolute phase of the fringes.

The r.m.s. noise after a 1-min integration was equivalent to ~ 0.06 Jy. 3C236 was observed for a total of 12 h on July 19, 1974, and the system was calibrated using 3C286 (assumed unresolved and having a flux density of 22 Jy). Three simultaneous delay channels were used. One was centred on the compact source and gave fringes throughout the observing period. The others were optimised for the two 'hot spots' at the extremities of the $39'$ source. According to Westerbork measurements at the lower resolutions, the flux densities of these bright regions at 610 MHz are 1.8 ± 0.2 Jy and 2.1 ± 0.2 Jy respectively. We found no fringes from the hot spots larger in amplitude than 0.10 Jy, indicating that most of their flux is emitted by a region larger than $1''$.

The baseline coverage at all three frequencies is plotted in Fig. 1 together with that obtained by Wilkinson^{1,2} at 1.423 GHz. The fringe amplitude data are shown in Fig. 2.

Derivation of the radio structure

Radio maps were made at both 2.695 and 8.085 GHz by Fourier transform of the visibility data and the subsequent use of the cleaning algorithm⁸, with Gaussian restoring beams of half-power widths $0.55''$ by $0.25''$ and $0.18''$ by $0.08''$, respectively, extended in p.a. 110° . Since we know *a priori* that the compact component is smaller than $1''$ and since the NRAO array has good amplitude and phase stability, the clean procedure can be validly used here. To help judge the reliability of the cleaned maps and to interpret the data at 1.4 and 0.4 GHz where only fringe amplitude data were obtained, we fitted the fringe amplitude data at all four frequencies to various models composed of elliptical Gaussian components.

The general features of the compact component in 3C236 are displayed in the 2.7 GHz map shown in Fig. 3a. The map shows two subcomponents of unequal intensity and size. The centres are separated by $\sim 0.8''$ in p.a. $\sim 120^\circ$. The easterly component is the stronger and is not highly resolved whereas the westerly component is extended with roughly the same orientation as the outer double. In Fig. 1 the line through the origin denoted by M_0 indicates the projected baselines at which the central visibility maximum should occur for a source elongated in (and symmetrical about) p.a. 122.5° . The positions of the fringe maxima and minima observed at 2.7, 1.4 and 0.4 GHz all agree with those expected from the separation and position angles defined in the map. The parameters of the best fitting double model are given in Table 1 and the fringe amplitude function predicted by this model is shown by the solid curve in Fig. 2b. This extent and position angle agree well with

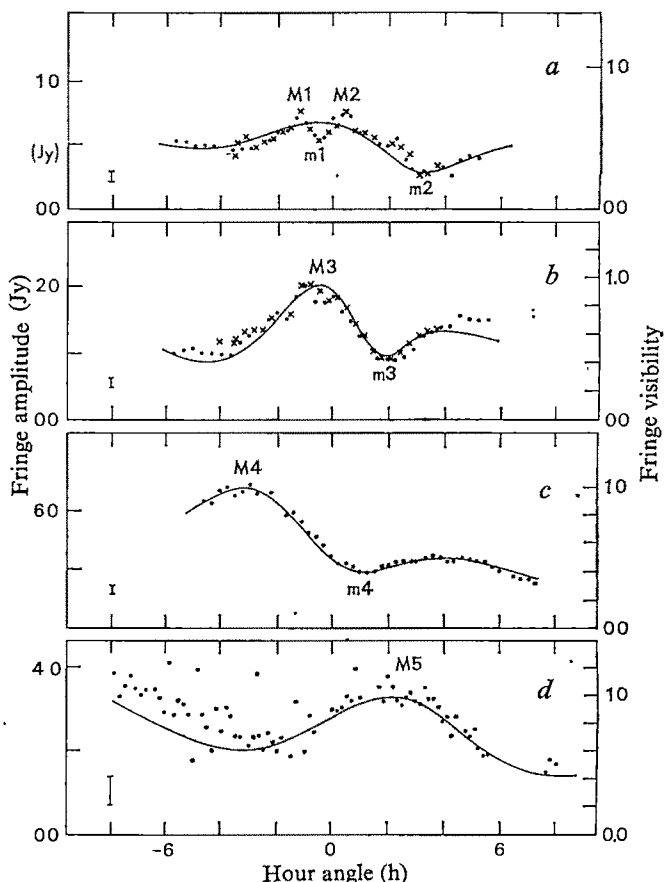

Fig. 2 Variation of fringe amplitude with hour angle at: a, 8.1 GHz; b, 2.7 GHz; c, 0.4 GHz; d, 1.4 GHz. For 8.1 and 2.7 GHz, only data from the longest of three almost equivalent baselines are shown. Bars indicate estimated total uncertainties (including systematic errors) in each fringe amplitude point. Solid lines show the fringe amplitude variations predicted by the models given in Table 1 (Fig. 2b, c, d) and Table 2 (Fig. 2a) \bullet , December 26; \times , December 28.

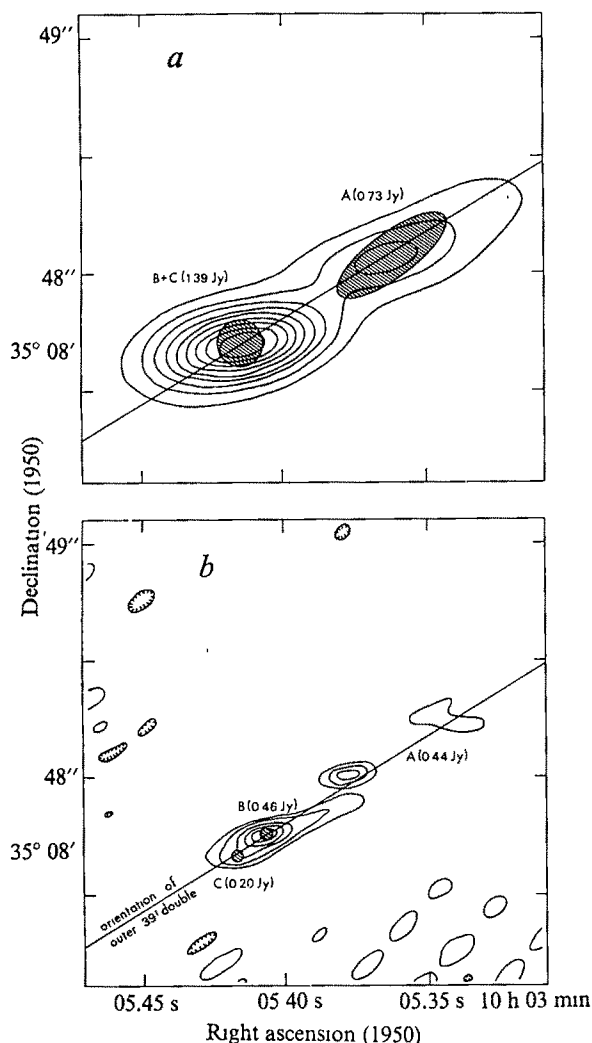

Fig. 3 Cleaned contour maps of the compact component at: *a*, 2.7 GHz with 10% contour levels; *b*, 8.1 GHz with 20% contour levels; and an additional level at 10%. The light lines at a position angle of 122.5° indicate the orientation of the 39' extended radio structure. The model brightness distribution given in Tables 1 and 2 are indicated by the shaded regions. The absolute positional accuracy is better than $0.05''$.

those previously derived from measurements at lower resolution^{1,9}.

Our observations at 0.4 GHz and those by Wilkinson at 1.4 GHz have smaller resolution than the measurements at 2.7 GHz. The fringe amplitude data are consistent with the double picture deduced from the data at 2.7 GHz. Taking the optimum 2.7-GHz model and changing only the flux densities of the subcomponents results in reasonable agreement with the observations at 0.4 and 1.4 GHz (see Fig. 2*c* and 2*d* and Table 1). There is no indication that the subcomponents have appreciably different spectra between 0.4 and 2.7 GHz.

In the case of the measurements at 8.1 GHz, the resolution is a factor of three higher and the interpretation of the structure is more complex. The easterly subcomponent dominates and is itself resolved into at least two parts denoted by B and C, separated by $0.16''$ in p.a. $121 \pm 10^\circ$. This is also apparent from the deep fringe amplitude minimum m2 and the subsequent rise in the 8.1-GHz data. The optimum parameters corres-

ponding to a point double model are shown in Table 2 and the corresponding fringe amplitude variation is plotted in Fig. 2*a*. The fit is good.

Both the map and fringe data show that the westerly component A is highly resolved. Two relatively weak hot spots are present on the map at low level but are somewhat uncertain. The effect of the westerly subcomponent in the fringe amplitudes can be seen as a weak beating near transit, corresponding to the maxima M1 and M2 and the minimum m1. This beating occurs only during a limited hour angle range because of the elongated nature of this subcomponent. The line joining the origin with the central maxima M3 and M4 in Fig. 1 intersects the 8.1-GHz baseline ellipses at a position corresponding to the fringe minimum m1. Therefore, the central maximum cannot be represented as a straight line in the u - v plane. This indicates that the structure is not completely linear. The brightest regions of the $0.8''$ source define a line which is slightly rotated with respect to that of the overall emission.

We can summarise our main conclusions (see Table 3) regarding the structure of the compact source in 3C236 as follows:

- (1) The overall brightness distribution displays a double but asymmetric characteristic.
- (2) The source extent is $\sim 0.8''$ (2 kpc).
- (3) The overall position angle is $121^\circ \pm 4^\circ$.
- (4) The easterly (brighter) subcomponent is resolved into two parts, B and C, each smaller than $0.05''$ (< 130 pc) and separated by $\sim 0.16''$ in p.a. $121^\circ \pm 10^\circ$.
- (5) The westerly component A is significantly larger, elongated by $\sim 0.6''$ (1.6 kpc) along the source axis. Perpendicular to this axis the extent is $\sim 0.1''$ (0.3 kpc). There is some indication of fine structure.
- (6) On a scale of $< 0.2''$ there is structure which is not symmetrical about the overall source axis. This asymmetry limits the accuracy of conclusion (3).
- (7) Between 0.4 and 2.7 GHz there is no appreciable difference between the spectra of A and that of (B+C).

Comparison with structure of outer radio double and optical galaxy

The 39' double structure in 3C236 has a well collimated appearance with bright frontal edges or hot spots. The two outer components have roughly equal flux densities at 610 MHz, but the westerly component is less highly collimated than the easterly one and its frontal edge is well resolved at 610 MHz with the $57'' \times 99''$ beam of the Westerbork telescope. With respect to the compact nuclear component the outer edges are located at $+24.1'$ in p.a. $122.7 \pm 0.5^\circ$ (east) and at $-15.5'$ in p.a. $121 \pm 2^\circ$ (west).

Note the following similarities between the structure of the 39' double and that of the compact nuclear component. First, the overall position angles agree to within 2° , better than the uncertainties. Second, the transverse size of the westerly structure is larger in both cases. At the position of subcomponent B the angle subtended by the westerly subcomponent A is $\sim 8^\circ$, roughly equal to the angle subtended by the outer westerly component. The radio source is identified¹¹ with a 16 mag elliptical galaxy having a redshift of 0.098. The extent of the galaxy is about $10''$ but the absolute positional accuracy of the available optical photographs is insufficient for a comparison with the radio map in Fig. 3. The galaxy is oriented in p.a. $30 \pm 5^\circ$ (A. Bridle, personal communication). Within the

Table 1 Double elliptical Gaussian model derived from 2.7-GHz data

measurement errors the elongation of the radio structure therefore lies along the projected minor axis of the galaxy.

Discussion

First consider whether the compact component should be interpreted as (1) the relic of a past event in the nucleus which simultaneously produced the outer components of 3C236, or (2) the product of recent nuclear activity.

It is unlikely that the compact component has been contained for a period exceeding $\sim 2 \times 10^7$ yr, the light travel across the whole source. Possible confining mechanisms¹⁰ include thermal pressure, ram pressure and inertia. They must provide a confining pressure which exceeds P_{min} , the minimum (equipartition) internal pressure in the subcomponents due to relativistic particles and magnetic field. For subcomponent A, $P_{\text{min}} \sim 10^{-8}$ dyne cm^{-2} and for subcomponents B and C, $P_{\text{min}} \sim 10^{-8}$ dyne cm^{-2} .

In the case of thermal confinement the pressure balance condition immediately yields a lower limit for the product of the density ρ and temperature T of the confining gas. Thus with $P_{\text{min}} = 10^{-7}$ dyne cm^{-2} , $\rho T > 2 \times 10^{-5}$ g cm^{-3} degree. Now if $T \gtrsim 10^7$ K the thermal velocities within the confining gas would exceed the escape velocity of the galaxy. Such a hot

the relativistic plasma is expelled must have remained constant to better than 4° over more than 2×10^7 yr. It is presumably the rotational axis of the galaxy or of some dense region inside its nucleus. Aligned recurrent expulsions are difficult to reconcile with the 'gravitational slingshot' model of Saslaw *et al.*¹⁴ in which massive objects are flung out in the rotation plane of the elliptical galaxy. Furthermore, the alignment of the radio components along the minor axis of the galaxy provides an additional argument against this mechanism.

One class of models requiring quasi-continuous nuclear activity, which recently received considerable attention, involves the continuous flow of energy from the nucleus to hot spots in the outer components of double radio sources¹⁵⁻¹⁷. This energy is efficiently transported in a narrow beam at relativistic speeds. All the schemes that have been proposed to produce such relativistic beams (rotating massive object¹⁵, Laval nozzles¹⁷ and so on) operate over distances $\lesssim 100$ pc. It is therefore unlikely that the entire 2 kpc 'compact' component of 3C236 could be associated with the production of the beam. But the radio emission could well be due to interaction of the beam with non-relativistic gas in the vicinity of the nucleus of the galaxy. A fraction of the bulk energy in the beam would then be randomised in the galaxy rather than in the outer regions of the beam and the galaxy would seem to 'glow' at radio wavelengths. In this case the detailed radio structure would merely reflect that of the entrained non-relativistic gas illuminated by the relativistic beam. Such a picture would be consistent with the remarkable alignment, the agreement between the angles subtended by the westerly 'cone of ejection'

Table 3 The major subcomponents in the radio nucleus of 3C236

	Half intensity diameters		Position angle	Position*		Flux densities (Jy)				Spectral index
	Major	Minor		East	North	8.1 GHz	2.7 GHz	1.4 GHz	0.4 GHz

*Position is given with respect to 2.7-GHz centroid (epoch 1950) $\alpha = 10 \text{ h } 03 \text{ min } 05.396 \pm 0.003 \text{ s}$, $\delta = 35^\circ 08' 47.84 \pm 0.03''$.

gas could not be maintained within the galaxy. An additional argument for even lower temperatures is provided by the presence of the [O II] $\lambda 3727$ line in the optical spectrum of 3C236 (refs 11 and 12). Taking $T < 10^7$ K gives $\rho > 2 \times 10^{-22}$ g cm^{-3} . Since the confining gas must be present over distances of at least 2 kpc ($\sim 0.7''$), a total mass of $> 10^{11} M_\odot$ would be required. Also, such large densities, with a magnetic field strength comparable to the equipartition value of $\sim 4 \times 10^{-4}$ gauss, would result in Faraday rotation of $\sim 10^8$ rad and complete depolarisation of the source at centimetre wavelengths. Since this component has been found to be polarised by $\sim 2\%$ at 6 cm (ref. 13 and Baker, unpublished) we discount the possibility of thermal confinement.

Ram pressure confinement would need even higher gas densities. Scaling a velocity $< c$ for the outer components to the compact central component results in an expansion velocity $v < 100 \text{ km s}^{-1}$. Since $\rho v^2 > 10^{-7}$ dyne cm^{-2} , $\rho \gtrsim 10^{-21}$ g cm^{-3} for confinement.

At first sight inertial confinement by a relatively cold gas inside the subcomponents seems more promising. Again taking $v < 100 \text{ km s}^{-1}$, this gas must have a total mass $> 2 \times 10^8 M_\odot$, corresponding to a density $\gtrsim 5 \times 10^{-26}$ g cm^{-3} . Since, for these densities also no polarisation should be measurable, inertia cannot provide the confining pressure. We have therefore shown that the compact central component of 3C236 is not confined and is unlikely to be a remnant of the event which gave birth to the large double radio source.

It is almost certainly the result of a relatively recent outburst in the nucleus of the galaxy. In this case, the axis along which

in the compact and extended structures and the observed asymmetry.

A more detailed picture of the compact component requires sensitive observations with even higher resolution. Measurements with VLBI techniques may reveal whether any of the subcomponents discussed here have even smaller scale features. Structure on a scale of $\lesssim 0.01''$ might relate to the origin of the radio event. In addition, an intensive optical investigation of 3C236 should be made. Photographs with a positional accuracy of $0.1''$ could be usefully compared with our radio data. Together with a spectroscopic study of the distribution of [O II] $\lambda 3727$ such observations should enable a clearer picture to be obtained of the dynamics and physical conditions within this remarkable galaxy.

We thank Professor Sir Bernard Lovell for allowing us access to the Jodrell Bank facilities, Drs H. P. Palmer, B. Anderson, R. Peckham and Mr B. Speed for help with the 408-MHz observations, Mr J. Coe and his group for their support of the NRAO radio link interferometer, and acknowledge comments from Professor Oort and Drs W. Brouw, G. de Bruijn, H. Habing, P. Haves, R. Strom and A. Willis. The NRA Observatory is operated by Associated Universities, Inc., under contract with the NSF.

Ligand-induced redistribution of lymphocyte membrane ganglioside GM1

Thomas Révész* & Melvyn Greaves

ICRF Tumour Immunology Unit, Zoology Department, University College, London WC1E 6BT, UK

Dynamic aspects of the binding of cholera toxin to lymphocyte membranes have been studied. We have shown that the receptor for this ligand—the GM1 ganglioside—can be laterally redistributed into aggregates and caps. Exogenous purified GM1 inserted into GM1-deficient human leukaemic cells can undergo a similar pattern of ligand-induced mobilisation. These observations may have important implications for both the general behaviour of cell surface glycolipids and the mode of action of cholera toxin on adenyl cyclase.

INTERACTION of divalent or polyvalent ligands (for example, antibodies, lectins) with cell surface structures on lymphocytes and many other cell types induces redistribution of the largely diffuse binding sites into clusters and into highly polarised single aggregates or 'caps'^{1,2}. The capping process is not fully understood but depends on active cellular metabolism and is probably regulated by microfilaments and microtubules³. These observations along with species antigen intermixing in mouse-man heterokaryons² provide visually dramatic evidence for a fluid mosaic model of cell membranes⁴. Lateral mobility of both proteins and lipids (which have similar diffusion constants) has also been demonstrated amply by electron spin resonance and electron magnetic resonance studies (reviewed in ref. 2).

A principal implication of membrane fluidity is clearly that translational movement induced by physiological ligands may facilitate molecular interactions that play a critical role in signal transduction across membranes.

Lipids may play a crucial role in cell surface receptor function by regulating molecular mobility and also by virtue of selective hydrophobic association with integral membrane proteins^{5,6}. The marked deficiency of several glycolipids, particularly the charged gangliosides, in virus and carcinogen-transformed animal cells⁷, in human leukaemia cells⁸, and in normal cells at particular phases of the cell cycle⁹, suggests that these lipids have an important role in growth control.

The ganglioside GM1 (monosialo-gangliotetraosyl-ceramide) is the natural receptor for cholera toxin¹⁰⁻¹² and it is now well established that cholera toxin (cholera toxin) exerts both its clinical effects (intestinal hypersecretion and diarrhoea) and its experimental effects (for example, induced steroidogenesis, inhibition of proliferation) through the activation of adenylate cyclase and accumulation of cyclic AMP¹³⁻¹⁵. Cuatrecasas and colleagues have proposed that lateral diffusion of cholera toxin-GM1 complexes within the plane of the membrane may lead to interaction with adenylate cyclase and that GM1 might play an important role not only in general growth regulation

but also in the coupling of hormone-induced responses¹⁶. Similarly, Field has suggested that cholera toxin may (through GM1) stabilise a catecholamine-sensitive conformation of adenylate cyclase in the turkey erythrocyte membrane¹⁷.

So far no demonstration of ligand-induced redistribution of a glycolipid has been reported. In view of the intriguing relationship between GM1 and adenylate cyclase it would be of considerable interest to determine conditions for redistribution of this glycolipid into aggregates and caps. A comparison of ganglioside and glycoprotein redistribution might reveal important implications for functional associations of gangliosides and proteins and information of relevance to signal transduction mechanisms in membranes. We demonstrate here, using cholera toxin and labelled antibodies as ligands, that GM1 on lymphocytes can indeed be redistributed into aggregates and caps, and moreover that GM1 inserted into GM1-deficient cells undergoes a similar pattern of ligand-induced redistribution.

Capping of lymphocyte membrane ganglioside

The experimental system for visualising the binding of cholera toxin to the lymphocyte surface is a three-layer immunofluorescence procedure (see legend to Fig. 2). Observations were performed using a Zeiss ultraviolet microscope with Plume, incident illumination and also the fluorescence activated cell sorter (FACS-1, Becton Dickinson, Mountain View, California)^{18,19}.

All lymphocytes, monocytes and granulocytes studied bound cholera toxin to their surface and uptake was rapidly saturated at 20 °C. Binding was inhibited by purified GM1 (Fig. 1). The biologically inactive cholera toxin bound almost as effectively as cholera toxin—as shown in other cell systems and expected from its competitive antagonistic capacity. At excess cholera toxin concentration there was no apparent difference between thymocytes, T and B lymphocytes; however, murine lymphocytes bound considerably more cholera toxin than human cells. We have shown previously that cholera toxin inhibits the proliferation *in vitro* of mouse T and B lymphocytes and L1210 lymphoma cells within a concentration range of 10⁻³–10⁻⁴ µg ml⁻¹ (ref. 8). The proliferation of human peripheral lymphocytes, however, was enhanced by these doses of cholera toxin, and only higher doses inhibited their mitogen-induced proliferative response.

Figure 2 illustrates the pattern of GM1 distribution observed on mouse and human cells incubated with different concentrations of cholera toxin. When all sequential steps were performed at 4 °C or at room temperature in the presence of 0.2 M sodium azide the distribution of fluorescence was either in aggregates of various sizes or, at higher concentrations (particularly on mouse cells), as intense rings. When all steps were performed at 37 °C on human lymphocytes very little surface fluorescence was detectable. We interpreted this observation as indicating that cholera toxin had been internalised rapidly or shed, and this view was supported by the following observations. When

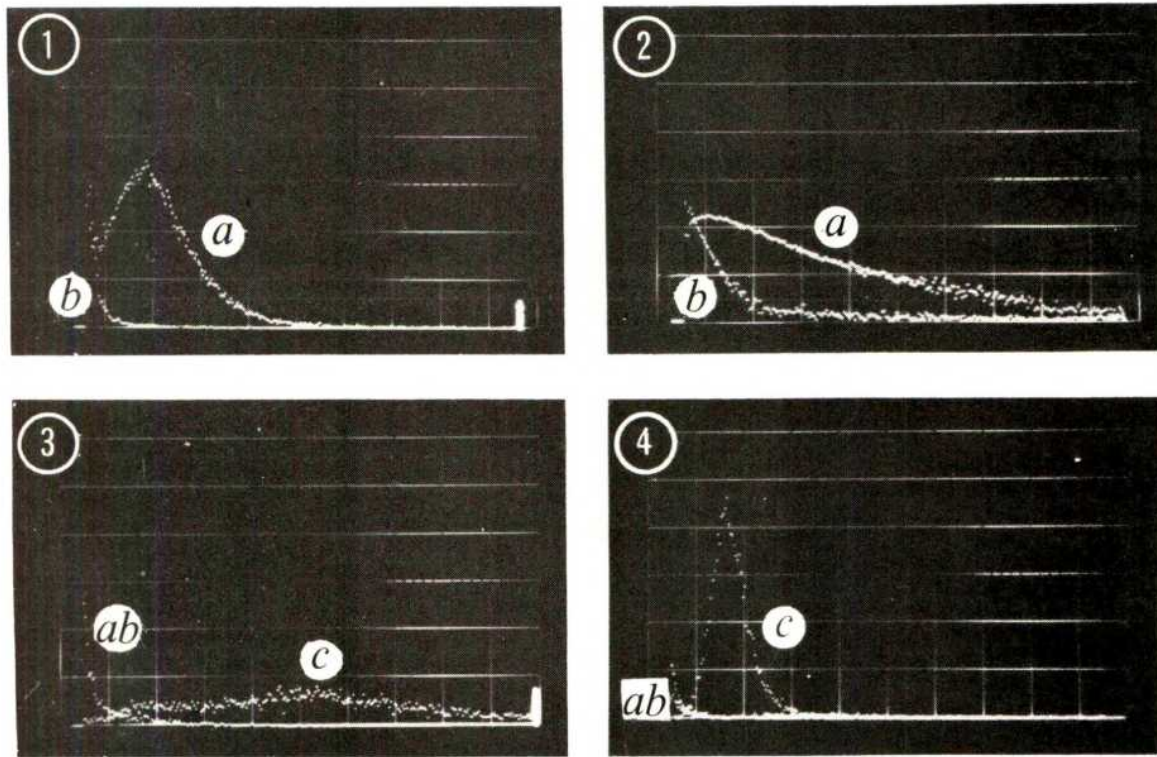

Fig. 1 Fluorescence activated cell sorter (FACS) analysis of cholera toxin binding to normal lymphocytes and leukaemic cells. The essentials of the immunofluorescence method are outlined in the legend for Fig. 2. Abscissa, relative fluorescence intensity; ordinate, relative number of cells, 10,000 cells counted in each sample. 1, Human thymus lymphocytes: *a*, cholera toxin; *b*, control (horse anti-cholera toxin and rabbit anti-horse- γ -fluorescein-isothiocyanate only). 2, Human tonsil lymphocytes: *a*, cholera toxin; *b*, cholera toxin preincubated with purified GM1 ganglioside. 3, Acute myeloblastic leukaemia cells: *a*, and *b* (superimposed), as in 1; *c*, cholera toxin binding after pretreatment of AML cells with neuraminidase (10 IU ml^{-1}). 4, Acute lymphoblastic leukaemia cells: *a*, and *b* (superimposed), as in 1; *c*, cholera toxin binding to cells that have incorporated exogenous GM1 (purified from brain—gifts from Drs R. Murrey and D. Critchley) into their surface membrane.

Fig. 2 Surface fluorescence pattern of human and murine lymphocytes labelled with cholera toxin. Cells in 0.2 ml Earl's saline ($2 \times 10^7 \text{ ml}^{-1}$) were incubated with cholera toxin ($100 \mu\text{g ml}^{-1}$) for 10 min at 4°C . After washing the cell suspensions twice, horse anti-cholera toxin serum was added in a final dilution of $1:10$, and the cells were incubated at 21°C for 30 min . Further washing was followed by a $1:10$ dilution of rabbit anti-horse- γ -globulin-fluorescein, isothiocyanate, and incubation at 37°C for 30 min . Washed cell suspensions were mounted on slides and examined using a Zeiss Ultraphot II microscope modified for epifluorescence microscopy. Photographs were taken with a Pentax camera. ($\times 524$). *a*, Human tonsil cells (phase contrast); *b*, human tonsil cells (fluorescence); *c*, murine spleen cells (phase contrast); *d*, murine spleen cells (fluorescence).

Fig. 3 Capping of cholera toxin on human and murine thymocytes. Lymphocytes in 0.2 ml Earl's saline (2×10^7 ml $^{-1}$) were incubated with various doses of cholera toxin for 10 min at 4 °C. Horse anti-cholera toxin was added to give a final concentration of 1:10, and cell suspensions were incubated at 21 °C for 30 min. The third incubation—with rabbit anti-horse- γ -fluorescein isothiocyanate was carried out at 37 °C for 30 min. Caps were defined as cell surface fluorescence restricted to one third or less of the cell surface. Open columns, human; black columns, mouse.

cholera toxin was added at 4 °C and either or both of the antibody layers at 37 °C, intense surface fluorescence was visible. The pattern of fluorescence as shown in Fig. 3 depended on the concentration of cholera toxin used and the species origin of lymphocytes. Human lymphocytes showed pronounced redistribution into discrete caps over a wide range of concentrations (compare Fig. 2) in contrast, mouse lymphocytes only showed caps with the lower concentrations used. Significantly, the biologically inactive cholera toxin gave essentially the same results as cholera toxin. By incubating mouse spleen lymphocytes with low concentrations (10^{-4} – 10^{-2} µg ml $^{-1}$) of cholera toxin at 37 °C followed by the two antibody layers at 4 °C in the presence of azide it was possible to demonstrate capping on approximately 50% of reactive cells. Although the intensity of cap fluorescence was less than when the second and/or third steps were performed at higher temperatures (compare Fig. 2), this result demonstrated that cholera toxin itself can induce redistribution into caps. We suspect that the lack of observable capping of GM1 on mouse lymphocytes treated with high concentrations of cholera toxin is related to a higher level of GM1 in these cells compared with human lymphocytes. Although we have not yet quantified cholera toxin binding sites on these cells, this interpretation is supported by the observation that capping of GM1 on human cells (at high cholera toxin concentrations) is inhibited by creation of more GM1 binding sites for cholera toxin. This was achieved both by neuraminidase pretreatment—which converts other gangliosides (that is GD1a, GT1; di- and tri-sialo-gangliosides) into GM1 by cleaving off sialic acid residues²⁰—and by direct insertion of GM1 into cells (Table 1).

Table 1 Inhibition of capping of GM1 on human tonsil cells

Pretreatment	% Capping
None	89.5
Trypsin (0.05%)	85.0
Neuraminidase (10 IU)	2.2
GM1 insertion (20 µg)	3.0
Colchicin (10^{-4} M)	86.5
Cytochalasin B (10 µg)	48.2
Colchicin (10^{-4} M)+ cytochalasin B (10 µg)	27.6

Human tonsil cells (2×10^7 ml $^{-1}$) were incubated with trypsin, neuraminidase and purified GM1 at 37 °C for 30 min followed by cholera toxin at 4 °C, horse anticholera toxin at 21 °C and rabbit anti-horse- γ -globulin-fluorescein-isothiocyanate at 37 °C. Colchicine and cytochalasin B were added to the appropriate cell suspensions 5 min before each step. Caps were defined as cell surface fluorescence restricted to less than one third of the cell surface.

Holmgren and colleagues recently reported on the distribution of mouse thymus lymphocyte GM1 using a triple layer system essentially the same as that reported here²¹. They observed both ring staining and aggregation, but in contrast to our results, no cap formation. The reported concentration of cholera toxin used in these experiments, however, was 1 µg ml $^{-1}$. As can be seen from Fig. 3, this dose is considerably above the maximal concentration for cap induction, in mouse lymphocytes.

Capping of immunoglobulin molecules on lymphocytes is inhibited by a combination of colchicine and cytochalasin^{22,23}. Although these drugs may have diverse effects on cells, these studies suggest that microfilaments and microtubules have an important role in molecular mobility in the membrane³. Significantly, these drugs have precisely the same effect on GM1 redistribution (Table 1); in combination they are more potent than either alone. Although GM1 is the biologically relevant receptor for cholera toxin and free GM1 can completely inhibit binding to cells (see above and refs 11 and 12), cholera toxin does bind at least weakly to other gangliosides and also to some glycoproteins. It was therefore theoretically possible that the capping we observed was not due to GM1 redistribution but to movement of other structures. The following experiment provides, however, an unequivocal demonstration of ganglioside redistribution into caps.

Gangliosides inserted into membranes

Many transformed animal cell lines are ganglioside deficient⁷, and we have reported that virtually all human acute leukaemia cells have a considerable deficiency in binding sites for cholera toxin⁸. These cells efficiently incorporate exogenous GM1 into

Fig. 4 Insertion and capping of purified GM1 in human acute lymphoid leukaemia cells. Leukaemia cells in 0.2 ml Earl's saline (2×10^7 ml $^{-1}$) were incubated with various doses of purified GM1 for 30 min at 37 °C. After washing the cells twice in Earl's saline cholera toxin (100 µg ml $^{-1}$) was added, followed by two antisera, as described in the legend for Fig. 2. Fluorescence staining patterns: Solid columns=ring (continuous surface staining—see Fig. 2); dotted columns=patchy (fluorescence aggregates of various sizes); stippled columns=caps (surface fluorescence restricted to less than one-third of the cell surface).

their membranes and bind cholera toxin^{8,24} (Fig. 1); alternatively, if they are treated with neuraminidase, cholera toxin binding occurs, presumably by the conversion of other gangliosides to GM1 (Fig. 1). We have performed similar experiments with the rodent cell lines BHK and NIL; however, because these cells are by chemical criteria deficient in all gangliosides²⁵ they can be rendered cholera toxin-reactive by GM1 insertion but not by neuraminidase treatment. After either GM1 insertion or neuraminidase treatment acute leukaemia cells show pronounced capping provided that not too much GM1 is inserted (Fig. 4); a result predicted by our earlier observations (compare Fig. 3). Although it is theoretically possible that GM1 insertion reveals endogenous non-GM1 binding sites for cholera toxin,

we regard this as extremely unlikely and therefore suppose that all the redistribution we observe is due solely to lateral mobilisation of the inserted GM1. These experiments provide compelling evidence for the lateral redistribution of glycolipids.

Possible mechanisms of glycolipid redistribution

The mechanics and molecular requirements for glycolipid redistribution are of course unknown. It is however possible to conceive of two basically different means by which a glycolipid such as GM1 might become capped. It may do so by association with integral proteins or a particular protein. Alternatively, glycolipids on motile lymphocytes might be in continual orientated motion, cross linkage by ligands then resulting in 'trapping' at the rear 'pole' of the cell. At present we have no unequivocal evidence which clearly supports either of these alternatives; distinguishing between them will perhaps have important implications for the dynamics and functional roles of lipids in cell membranes. The capping process is insensitive to trypsin (Table 1) and so we assume that if GM1 did have an obligatory association with an integral protein then the latter structure is trypsin insensitive—at least as far as its facilitative interaction with GM1 is concerned.

Since exogenous GM1 molecules inserted into membranes can be redistributed instantly we must also assume that any specific conditions necessary for mobilisation would have to be established rapidly by newly incorporated molecules. It is particularly relevant in this respect that at least some of the GM1 molecules and other glycosphingolipids incorporated into the membrane of glycolipid-deficient transformed cells can alter growth characteristics²⁶ and render cells sensitive to the biological effect of cholera toxin²⁴. The aggregation of GM1 molecules into clusters and caps which is induced by 'physiological' concentrations of cholera toxin may be very relevant to the regulation of adenylate cyclase activity as suggested by Cuatrecasas and colleagues. But since the biologically inactive cholera toxinoid has virtually the same binding capacity as cholera toxin and can also induce redistribution of GM1 (see

above) it would seem that aggregation of GM1 molecules is not in itself sufficient to alter adenylate cyclase activity.

T.R. was supported by a research training fellowship awarded by the International Agency for Research on Cancer and M.G. by the ICRF. We are grateful to Drs R. Murrey (University of Toronto), D. Critchley (ICRF, Lincoln's Inn Fields) and M. Raff (University College, London) for gangliosides, cell lines and helpful discussion. We thank David Capellaro for help with FACS analysis and Dr A. Lister for most of the leukaemia cell samples.

Genetic perturbations that reveal tertiary conformation of tRNA precursor molecules

William H. McClain & J. G. Seidman

Department of Bacteriology, University of Wisconsin, Madison, Wisconsin 53706

The ubiquity of tRNA-like conformations in tRNA precursors of prokaryotes provides a common structural basis for precursor recognition by the maturation enzymes. This design eliminates the need for multiple enzymes to achieve the maturation of different precursors. Moreover, the requirement of this specific conformation for maturation guards against the production of potentially deleterious mutant tRNAs.

THE salient features of tRNA biosynthesis in prokaryotic organisms are fairly well understood. The process begins by transcription of a tRNA gene to yield a large precursor RNA, which is then converted into tRNA by a series of enzymatic steps that include the modification of specific nucleotides and cleavage of the precursor RNA. The absence of inaccurately processed precursor RNAs in normal cells demonstrates the accuracy of this multi-step process. Such specificity must be determined in part by precursor RNA conformation, so it is at this level of complexity that we must investigate the mole-

cular mechanism that guarantees accurate tRNA synthesis. Precursor RNA conformation and its relation to tRNA biosynthesis are the subjects of this report.

The original observation on which our experiments were based is that mutationally altered forms of phage T4 glutamine tRNA contain reduced levels of modified nucleotides¹. Since modification depends on conformation, these mutants might be used for indirect study of precursor RNA conformation. Modified nucleotides are formed at the level of precursor RNA by enzymatic modification of one of the standard nucleotides. Comparison of many tRNA sequences indicates that the formation of modified nucleotides rarely if ever involves enzymatic recognition of the primary nucleotide sequence alone². These considerations and other kinds of evidence³ indicate that recognition relies on the secondary and possibly tertiary conformations of the RNA molecules. The lack of modified nucleotides in mutant glutamine tRNAs therefore implies the existence of distorted conformations of the corresponding precursor RNAs, which contain glutamine and leucine tRNA sequences^{4,5}. These considerations raise an interesting question. Are deficiencies in nucleotide modifications

confined to the glutamine tRNA region of the precursor RNA or are they also present in leucine tRNA? This obviously will depend on the specific conformation of the precursor RNA at the time its nucleotide residues are modified, as illustrated by the following example. If there is little or no interaction between the residues of the two tRNA sequences, as would be the case with two cloverleaf secondary structures, then only glutamine tRNA will be deficient in nucleotide modifications. By contrast, if there are extensive interactions between the residues of the two tRNA sequences, then the modified residues of both tRNAs will be deficient in the mutants. We have tested these possibilities by isolating mutant precursor RNAs and determining their content of modified nucleotides. As viewed by this kind of analysis the conformation of the precursor RNA involves little or no interaction between the residues of the two tRNA sequences.

Mutant-specific patterns

Precursor RNAs labelled with ^{32}P were purified to more than 80% radiochemical homogeneity by two successive steps of polyacrylamide gel electrophoresis. They were then analysed for modified nucleotides. Table 1 gives the percentages of modification at twelve positions in the glutamine-leucine precursor RNA that is synthesised after infection of *E. coli* by the psu_2^+ ochre-suppressing strain of phage T4. psu_2^+ is the structural gene of an ochre-suppressing glutamine tRNA¹. A value of 100% in

Fig. 1 Positions of modified and mutant nucleotides in glutamine-leucine (a) and proline-serine (b) precursor RNAs. Other residues are omitted. The phosphate-sugar backbone of the tRNA sequences is designated by the thick continuous line that is arranged in a double cloverleaf conformation. Hydrogen bonds involved in maintaining the cloverleaf conformations are designated by the short thin lines that are parallel. The 5' to 3' polarity of the RNA chains is indicated. Residue N_1 at the top left is in the anticodon of the psu_2^+ glutamine tRNA sequence¹, and N_2 on the right is in the anticodon of leucine tRNA¹⁷. At the bottom left N_3 is in the anticodon of the proline tRNA sequence^{6,7}, whereas $Cm^{2'}$ and A^* bracket the anticodon of the psu_1^+ serine tRNA^{6,9}. Arrows show nucleotide substitutions in the individual mutant of psu_2^+ (top) or psu_1^+ (bottom). All mutants have been described previously^{1,4,9} except for $72U$, a newly-isolated mutant of psu_2^+ (our unpublished results).

Table 1 Percentage of nucleotides that are modified in glutamine-leucine precursor RNAs

Glutamine tRNA nucleotide (position)	RNase fragment analysed	psu_2^+		$psu_2^+ - U11$	
		1 (%)	2 (%)	1 (%)	2 (%)

Standard nucleotide abbreviations³ are used except that N_1 and N_2 refer to the modified residues of unknown identities that are located in the anticodons of glutamine¹ and leucine¹⁷ tRNAs, respectively. In the first column position refers to the number of residues that a nucleotide is removed from the 5' phosphate of the mature tRNA sequence. The ^{32}P -labelled precursor RNAs were isolated after infection of the ribonuclease P-deficient strain A49¹³ and were purified by polyacrylamide gel electrophoresis^{7,10}. Wild-type B/5 strain was used as the host for psu_2^+ mutant $72U$ (Fig. 1), since this precursor RNA does not accumulate in A49 cells (our unpublished results). Modification percentages were determined by analysing the RNase A or T₁ fragment, derived from a two-dimensional fingerprint, that is indicated (fragment designations are defined elsewhere^{1,12}). The analyses involved digesting the appropriate fragment to mononucleotides with RNase T₂, fractionating the products by two-dimensional, thin-layer chromatography and then comparing the amount of ^{32}P radioactivity in modified and unmodified residues⁷. Modified residues at a level of 100% contained about 400 c.p.m.; the lower limit of detection was about 2%. Different precursor RNA preparations were used for experiments 1 and 2. In precursor RNA, glutamine and leucine tRNAs both contain the sequence GT Ψ CG; values for the Ψ s of these two sequences were not determined because the two Ψ s are in identical RNase A and RNase T₁ fragments and therefore cannot be distinguished. No evidence of modification (that is, < 2%) was observed for glutamine tRNA residue m^2A (position 37) or for leucine tRNA residues D (position 17) and $Gm^{2'}$ (position 18).

Table 1 means that all the precursor RNA molecules contain the modified residue in question. Values that fall between 2%, the lower limit of detection, and 100% reflect heterogeneity in the precursor RNA preparation with respect to a particular modified residue. Table 1 shows that the values obtained with two preparations of precursor RNA are fairly reproducible for most of the residues. We do not know if the observed fluctuations reflect genuine differences in the precursor RNA preparations or inaccuracies in the measurements. For our purpose these fluctuations are small and do not affect the validity of the major conclusions presented below.

Table 1 shows a similar set of duplicate measurements for strain $psu_2^+ - U11$. The loss of psu_2^+ ochre-suppressing activity in this strain results from a C to U mutation at the 11th nucleotide from the 5' end of glutamine tRNA¹. We see that many of the modified residues are reduced in amount or are entirely absent in the $psu_2^+ - U11$ precursor RNA. Note the asymmetry in the reductions and that they are confined to the part of the precursor RNA sequence containing glutamine tRNA.

Further evidence for localisation of the effect of a mutation is provided by analysis of three additional mutants of psu_2^+ . Mutants $psu_2^+ - A40$ and $psu_2^+ - U62$ involve nucleotide changes in glutamine tRNA¹, whereas mutant $psu_2^+ - 72U$ has a C to U change at position 72 in leucine tRNA (our unpublished results). The change in notation with strain $psu_2^+ - 72U$ indicates that the mutant nucleotide is not in the sequence of the glutamine suppressor tRNA. Precursor cleavage yielding glutamine and leucine tRNAs is drastically reduced in mutant $psu_2^+ - 72U$, which explains why this strain lacks the suppressing activity of glutamine tRNA. The top panel of Fig. 1 gives the relative positions of mutant and modified nucleotides in the glutamine-leucine precursor RNA. Figure 2 is a graphic representation of

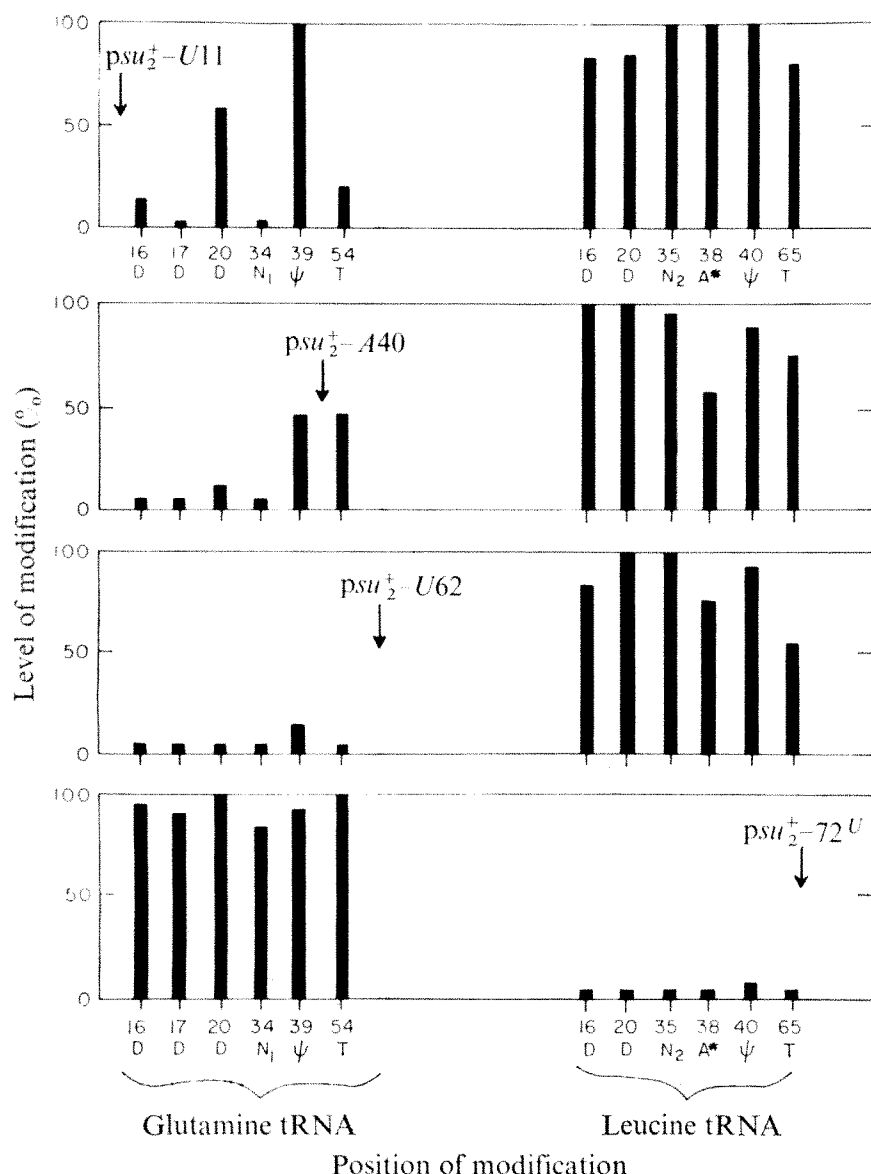

Fig. 2 Patterns of modified nucleotides in mutant glutamine-leucine precursor RNAs. The top panel displays the data in Table 1. The horizontal axis arranges the modified nucleotides with their respective residue numbers such that left to right corresponds to the 5' to 3' polarity of the RNA chain. The vertical axis gives the levels of modifications as percentages of the psu_2^+ values. The arithmetic means of the duplicate determinations were used. The vertical arrow in the top panel shows where the *U11* mutation is located relative to the modified residues. The remaining panels at the bottom show analogous results obtained from single determinations with three other mutants of psu_2^+ .

the modification levels in the four psu_2^+ mutant precursors compared with the level of the corresponding residue in the psu_2^+ precursor. The figure shows that deficiencies are confined to the tRNA sequence containing the mutant nucleotide. This is a clear demonstration of the independence of the two tRNA sequences at the time nucleotide modifications are introduced into the precursor RNA.

We obtained analogous results with the proline-serine precursor RNA that is synthesised after T4 infection^{6,7}. psu_1^+ is the structural gene of an amber-suppressing serine tRNA^{8,9}. Three suppressor-negative mutants of psu_1^+ involving nucleotide substitutions in serine tRNA (Fig. 1, bottom panel) were examined. Predictably, the mutant precursors were only deficient in nucleotide modifications in serine tRNA (Fig. 3).

Double cloverleaf conformation

The results in Figs 2 and 3 show that the major reductions in nucleotide modifications of precursor RNAs are confined to the tRNA sequence bearing the mutant nucleotide. There is no evidence that a mutation can have a significant effect on the formation of a modified nucleotide in the neighbouring portion of the precursor RNA containing the non-mutant tRNA sequence. These results demonstrate an independent substrate structure of the two tRNA sequences, and thus provide strong indirect evidence that the conformations of the precursor RNAs are predominated by interactions between the residues of the

individual tRNA sequences. Although the data do not specify the specific residue interactions, we suspect that they are quite similar to those found in the mature tRNAs. Such a conformation seems likely because both precursors contain only a few nucleotides in addition to those of the mature tRNAs⁵⁻⁷. We do not know the tertiary conformations of the tRNAs under consideration. The secondary structures are, however, sufficiently defined to allow for the proposal that the glutamine-leucine precursor RNA and the proline-serine precursor RNA will consist of pairs of tRNA-like cloverleaf entities as shown in Fig. 1. Although our results strictly refer to the conformations at the time of nucleotide modification, it is likely that a similar folding will characterise the molecules subsequently. Incidentally, the importance of the tertiary interactions within each cloverleaf to the substrate structure of the tRNA is documented by the absence of numerous modified nucleotides in the mutant tRNA sequences (Figs 2 and 3).

Several additional features of Figs 2 and 3 require comment. The first is the fractional modification of some residues (for example, glutamine tRNA residues D16, D20, Ψ 39, and T54 in mutant psu_2^+-U11). These patterns are mutant specific and presumably reflect the presence of residual precursor RNA conformations that are sufficient for modification of only a fraction of the precursor RNA chains. Such an explanation may be less likely when the same residue is fractionally modified in two or more mutants (for example, glutamine tRNA residue

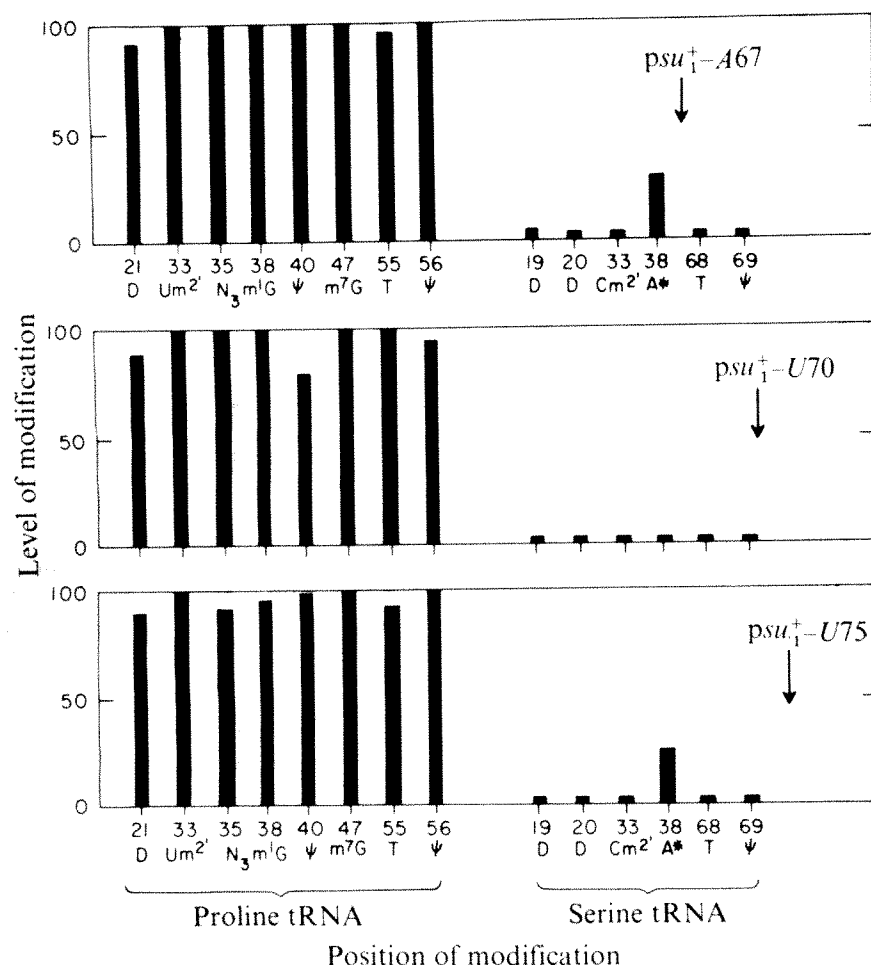

Fig. 3 Patterns of modified nucleotides in mutant proline-serine precursor RNAs. The levels of modified nucleotides are expressed as percentages of the values obtained with the psu_1^+ precursor RNA. All results were obtained from single determinations. The psu_1^+ values were similar to those reported previously⁷.

Ψ39 and serine tRNA residue A*38). In these cases either the recognition sites for the modifications are somewhat smaller and less specific in detail than with other residues, or there is an excess of these modification enzymes. Finally, there are indications in Figs 2 and 3 of slight reductions in nucleotide modifications in the non-mutant tRNA sequence (for example, leucine tRNA residues D16, A*38, and T65 in mutant psu_2^+ -U62). We do not know if these result from trivial inaccuracies in the measurements or reflect tertiary interactions between the two cloverleaf entities that influence the extent of modification. The latter possibility is potentially quite exciting, since it might offer an approach to the study of tertiary conformations of the precursor RNAs. Further experiments are in progress.

Implications for tRNA biosynthesis

Our proposal that precursor conformation closely resembles that of the mature tRNAs provides a molecular basis for understanding some of the precursor RNA biosynthetic details elaborated previously. Cleavage by ribonuclease P in the central region of the proline-serine precursor RNA is dependent on a specific nucleotide sequence at the distant 3' end of the RNA chain¹⁰. The secondary interactions of the cloverleaf bring these two distant regions of the RNA chain together, thereby enabling a single ribonuclease P molecule to interact with them as substrate for cleavage.

More generally, we suspect that a tRNA-like conformation will characterise many prokaryotic precursor RNAs. Consequently precursors of entirely different nucleotide sequences will nevertheless have similar conformations. This kind of conformational uniformity provides a common basis by which the numerous maturation enzymes can specifically recognise and handle many different precursor RNAs. The potential genetic economy that this provides is significant, since only a small amount of DNA is needed to specify an array of enzymes for maturation of many precursor RNAs. Our proposal is sup-

ported by several types of experimental results. Chang and Smith¹¹ have shown by *in vitro* chemical reactivity of the surface nucleotides that the precursor to *Escherichia coli* tyrosine tRNA has the same conformation as mature tyrosine tRNA. Unlike the phage T4 precursors described above, the tyrosine precursor contains a single tRNA species, but its maturation nevertheless involves the participation of ribonuclease P (ref. 12). Moreover, conditionally lethal mutants of *E. coli* defective in ribonuclease P fail to synthesise all tRNA species in the non-permissive conditions, and instead accumulate precursor RNAs containing one or more tRNA sequences¹³. Thus ribonuclease P is involved in the processing of precursor RNAs of diverse sizes and sequences, and it is presumably able to accomplish this by recognising the tRNA conformations in the precursor RNAs. In addition, accumulation of many different precursor RNAs in the absence of other participating maturation enzymes has also been demonstrated^{10,11,15}. Finally, the requirement of a native conformation in the precursor RNA for a productive interaction with the maturation enzymes is demonstrated by what happens when mutations like those shown in Fig. 1 destroy the conformation: they block the conversion of precursor RNA into tRNA^{1,8,9,16}. Such a safeguard for eliminating potentially deleterious tRNAs before they are functional may in part explain why precursor RNAs were implemented for the synthesis of tRNAs.

These studies were supported by a career development award and a research grant from the US National Institute of Allergy and Infectious Diseases.

letters to nature

Candidate for LMC X-5

A NEW X-ray source in the Large Magellanic Cloud, LMC X-5, has been reported¹. I wish to draw attention to the close proximity of the radio sources MC32 and MC33 to the best X-ray position. According to the positions of MC32/33 given by McGee *et al.*² they lie just outside the X-ray 90% confidence level error box for LMC X-5. In Fig. 1 I show the 6-cm radio contours of MC32/33 from ref. 2 with the X-ray error box superimposed on a plate of the region.

MC32/33 is one of six double radio sources found in the LMC by McGee and Newton³ to have one thermal and one non-thermal component. The non-thermal component (MC32) has a radio spectral index of -0.64 between 6 and 73 cm, not very different from the average value of -0.48 found by Milne⁴ for galactic supernova remnants. The association of another of these double radio sources, MC76/77, with the X-ray source LMC X-1 has previously been suggested⁵. This latter suggestion has been subsequently strengthened by X-ray observations of improved positional accuracy⁶.

Optically MC32/33 is identified with the H II region N44 of Henize⁷. Isophotes of the northern half of N44 (MC32) by

Dickel⁸ show it to have a ring-like structure which may strengthen the supernova interpretation of the object. LMC X-5 is probably a highly variable X-ray source as evidenced by the failure to detect it with Uhuru. This would imply that the X rays are emitted by a compact object (such as a neutron star) which might be expected in association with a supernova remnant.

The region around N44 is rich in early-type stars. Many X-ray sources have been identified with binary stellar systems, one component of which is a compact object and the other an early type star. One star is of particular interest—No. 73 in Sanduleak's⁹ list (indicated in Fig. 1 as Sk73) of LMC early-type stars between -68° and -69° declination. Spectroscopic observations by Feast *et al.*¹⁰ (their No. R99) indicate an emission spectrum with no visible absorption spectrum. Contamination by nearby nebulosity is an unlikely source of the emission features as the nebulosity is extremely weak in the immediate area of Sk73. I note that the He II $\gamma 4686$ line is present, a line which is frequently observed in emission in the X-ray binary stars. Photoelectric observations^{10,11} do not indicate any large amount of variability but the star may have an ultraviolet excess for its $(B-V)$ colour¹¹. Photographic photometry carried out on ADH plates (loaned by Armagh Observatory, N. Ireland) do not indicate variability in B magnitude of more than 0.15 mag.

Internally heated convection in the atmosphere of Venus and in the laboratory

IN this letter I draw attention to the possibility that the cellular convection observed by Mariner 10 in the subsolar region of the atmosphere of Venus may be related to laboratory studies of convection with internal heat generation.

Significant regions of the Venusian convection show cellular arrays^{1,2} indicative of some form of "Bénard convection", in the general sense of convection deriving from instability of the vertical temperature gradient. The fact that the convecting region is roughly centred on the subsolar point suggests that

this unstable stratification is generated directly by solar radiation. The Venera 8 observations³ of the attenuation of sunlight with decreasing altitude show that most of the radiation absorbed by the planet is in fact absorbed in the cloud layers. On the other hand, they also show that an earlier view that it might all be absorbed very close to the cloud tops was incorrect, as is, in any case, implied by the occurrence of convection. A detailed distribution of the absorption with respect to altitude cannot be inferred from the Venera 8 observations, because of the unknown relative importance of absorption and scattering in different layers⁴. But it is highly probable that the convection is being driven by solar heating within the convecting fluid. Although cellular convection is commonly associated with the convecting layer being heated from below, it is now known to occur also in internally heated layers. Moreover, in an important respect (that is, the "elongation" of the convection cells), the Venusian convection has a closer resemblance to laboratory convection of the latter type than of the former.

The "elongation" of the convection cells means that their horizontal scale is large compared with the depth of the convecting region. The cells in the Venusian atmosphere have a horizontal size¹ (presumably to be interpreted as about twice the distance between fastest rising and fastest falling fluid) of typically 200 km; some are as large as 500 km. The top of the convecting region is thought to be at an altitude^{1,5} of 63 km. It is possible that the convection extends down to the surface of the planet, but more likely it is shallower. The Venera 8 observations³ indicate that there is no significant heat absorption below an altitude of 35 km; further analysis of these observations⁴ places the bottom of the absorbing region at any altitude between 35 km and 48.5 km. It is also possible⁵ that the temperature gradient is subadiabatic below about 45 km, although evidence on this point is contradictory³. One should further take into account the fact that the scale height of the atmosphere (about 15 km) is not large compared with the other lengths involved. The effect of this is not well understood. It will presumably tend to reduce the vertical size of the convection cells—since, in order of magnitude, one expects this size to be the smaller of the scale height and the depth of the unstably stratified region—but the modifications to the flow may be relatively minor⁶. In summary, therefore, it is apparent that, whatever method one uses to infer the vertical scale of the convection, this scale is certainly much smaller than the horizontal scale of the larger cells and probably significantly smaller than that of a typical cell. This contrasts with previous suppositions about the likely structure of convection in the Venusian atmosphere⁷.

Correspondingly, in laboratory studies of cellular convection, it was supposed that the horizontal and vertical dimensions are normally roughly equal until experiments were performed with internally heated layers⁸. Convection cells in the classical situation of a fluid layer heated at a lower boundary and cooled at an upper boundary do grow horizontally with an increasing Rayleigh number⁹, but not so much as to affect seriously the above supposition. Experiments^{8,10} with an internally heated layer, thermally insulated at the bottom and cooled at the top, give a much more dramatic growth of horizontal cell dimensions. Cells with the centres of the rising and falling regions separated by a distance of five times the layer depth have been observed, although a factor of three may be considered more typical. (A more detailed study of this situation has been made (T. Hooper and D. J. T., unpublished); some of the statements in this letter draw on those results.) Similarly elongated cells have been observed in experiments¹¹ with boundary conditions such that the convecting region lies above a stably stratified region, a case in which both horizontal and vertical cell dimensions are free to adjust.

(It should be mentioned that the interpretation of some of the experiments has given rise to some controversy¹², primarily due to the failure of theoretical work to predict the observed elongation. My reasons for believing that the observations nevertheless provide the best starting point for comparison

with natural situations will be developed elsewhere. In summary, it may be said that most of the theoretical calculations were done in a way that could not show the effect or else contained oversimplifying assumptions. A qualitatively similar, although quantitatively smaller, discrepancy between theory and experiment exists in the case of a fluid layer heated from below and cooled from above; in that case, possible causes of the disagreement on the experimental side have been much more carefully eliminated.)

It thus seems likely that, despite the small scale height and other probable complexities of the former, the basic dynamics of the Venusian convection and of the laboratory convection are similar. Quantitative comparison would imply that the larger cells in the Venusian atmosphere extend down to close to the surface, whereas the smaller ones may be vertically limited in one of the ways mentioned above. But it may well be that greater elongations than have been observed in the laboratory can occur—the dynamics of all sufficiently elongated cells being broadly similar—and thus that the convection is entirely confined to an upper atmospheric layer. Elongated cellular convection is observed in the laboratory only for a range of the Rayleigh number; we are thus supposing that small scale turbulence ("eddy viscosity" and "eddy conductivity") provides dissipative effects of the appropriate magnitude, but such a supposition is necessitated by the observation of any type of cellular convection.

Comparison of other aspects of the Venusian and laboratory convection shows general consistency. Some of the Venusian cells are polygonal, others have a more streaky appearance. In the laboratory, both polygonal and roll-like cells have been observed over different Rayleigh number ranges. The Venusian cells have highly structured interiors. In the laboratory, cells with an elongation (as defined above) of greater than about two develop an internal structure; a prominent feature is the intermittent ejection of cold blobs of fluid from the region close to the upper boundary, similar to those found in recent computational studies¹³. But these features do not sufficiently distinguish this type of convection from other types for them to be taken as supporting the main thesis of this letter.

If developing understanding of the Venusian atmosphere confirms the idea that the convection is, in its basic dynamics, similar to the laboratory convection, this may have significant implications for other situations. In particular, it may encourage application to the interior of the Earth, for which the relevance of the laboratory experiments is at present a matter of discussion¹³⁻¹⁶.

The fact that mesoscale convection in the Earth's atmosphere exhibits elongated cells¹⁶ provides a further point of comparison. The dynamical processes involved are not understood, although it is usually supposed that the elongation results from anisotropy of small scale turbulence. It is worth noting, however, that a model of mesoscale convection involving volume heat sources due to latent heat release has been developed¹⁷. The model is very different from the laboratory situation considered above—in that the heating is non-uniform and cooling due to evaporation is also involved—but it does lead to the speculation that the laboratory experiments may have closer relevance to the Earth's atmosphere also than was previously supposed⁸.

I thank Dr P. A. Davies, Mr J. L. Turner and Dr N. O. Weiss for discussions.

Duration of equatorial spread F

It is well established¹⁻³ that the spread-F phenomenon, which is observed as diffuse echoes on the ionograms is a common feature during night time between the dip latitudes 20°N and 20°S. Based on the study of ionograms and published monthly f_oF_2 bulletins, morphological features of spread F have been reported for several equatorial stations^{1,4-10}. Equatorial spread F as seen on the ionograms generally starts around the time of reversal of the F-region vertical motion in the evening and

continues to grow in intensity during the downward motion of the F region¹¹. Usually spread F persists only for few hours and on some occasions continues throughout the night. Sometimes, after the disappearance in the pre-midnight period, spread F reappears in the post-midnight period.

We have examined the published ionospheric data of Trivandrum (dip latitude 0.6°S, Geographic Longitude 76°52'E) for the year 1970 to study the factors influencing the duration of spread F and the results are presented in this communication. The duration of spread F is determined by using the ionograms taken at 15-min intervals. The parameter $h'F$ is taken to represent the height variations of the F region. In the year 1970 there were about 30 nights in which spread F started in the evening hours (≈ 1900 IST) and continued until the early morning. The $h'F$ variations with time have been examined for all these nights. Figure 1 shows a plot of the hourly variation of $h'F$ for ten typical long duration spread-F nights. Plotted in the same graph are the $h'F$ variations for some of the nights in which spread F was present only for 2-3 h, to compare with

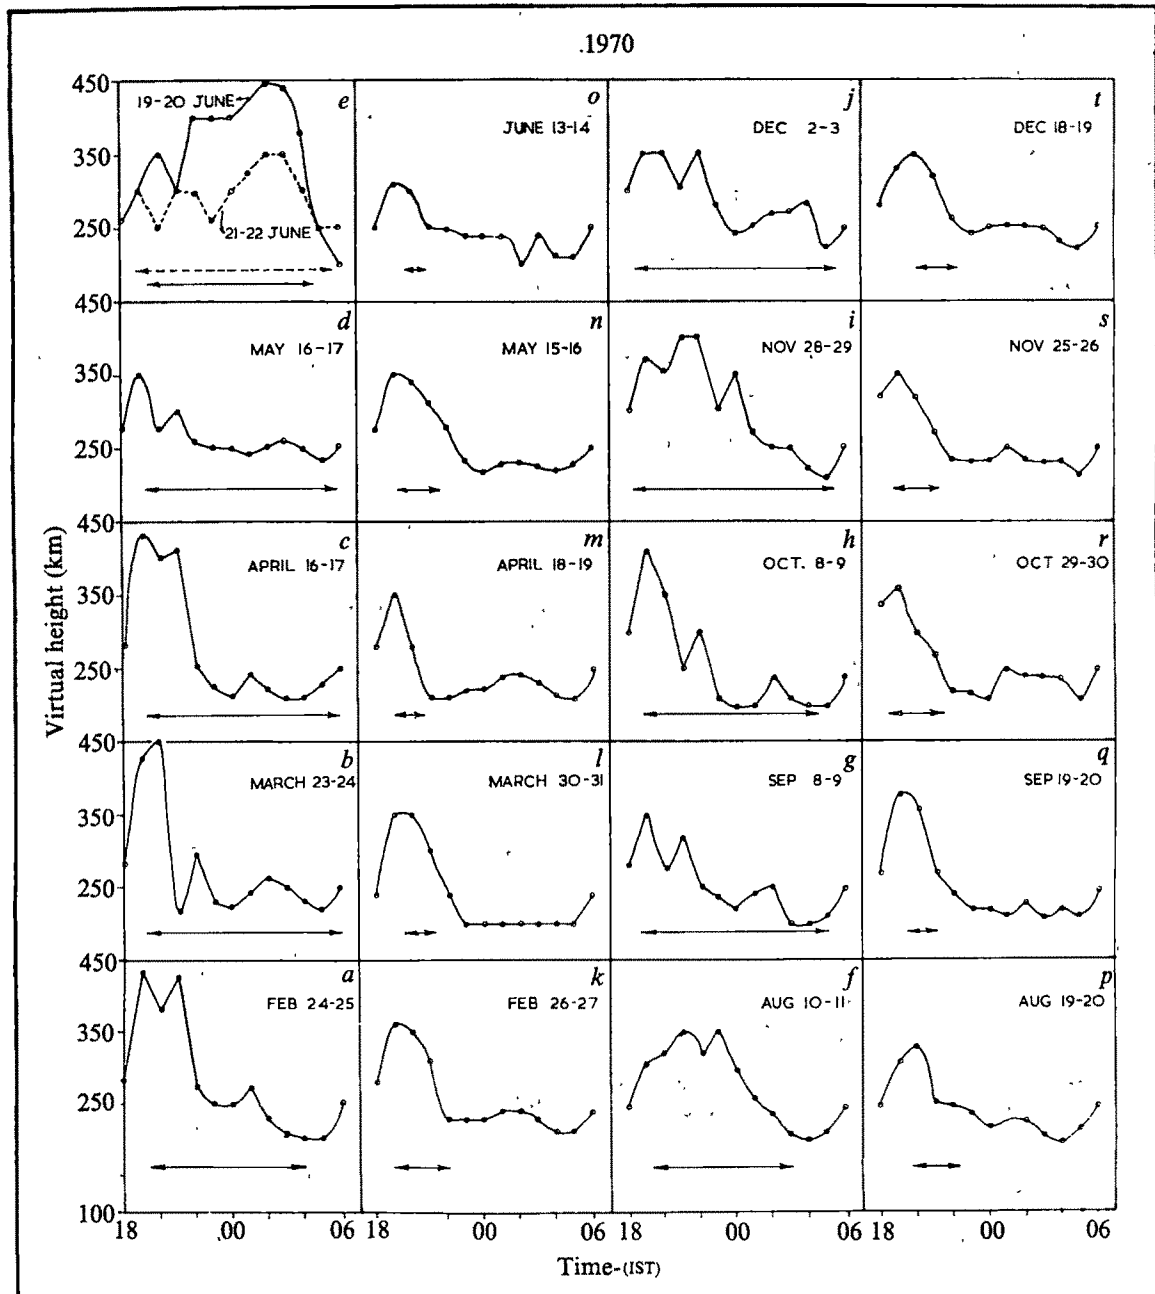

Fig. 1 $h'F$ variations during short and long duration spread-F nights. a-j, Long duration spread F; k-t, short duration spread F (2-3 h).

the $h'F$ variations during long duration spread-F nights. The duration of spread F is indicated by a line with arrows in these graphs. All the nights considered correspond to undisturbed magnetic conditions as indicated by the K_p index. Further, we have considered in this study only those nights with continuous duration of spread F. The main features of Fig. 1 are:

(1) $h'F$ starts rising from 1800 IST on all the nights shown and the onset of spread F is generally around the time of maximum $h'F$.

(2) The most striking feature is that on nights of long duration spread F, $h'F$ shows significant fluctuations. In many of these cases $h'F$ shows two peaks separated by about 1–2 h and another peak generally in the post-midnight period. On the other hand, on nights with short duration spread F, $h'F$ shows only a single maximum around 1900 IST and does not show any significant fluctuations. This is a consistent feature observed on all the nights in the year 1970 when spread F is present.

(3) On all the nights shown in Fig. 1, $h'F$ reaches approximately the same maximum height irrespective of the duration of spread F except in four cases.

(4) It is interesting that on August 10–11, 1970 (Fig. 1f) spread F continued for relatively shorter duration compared with other long duration nights and on this night, the $h'F$ fluctuations are not as prominent as they are on other nights of long duration spread F.

From an examination of the $h'F$ data on spread F nights for the whole year, it is found that even when the $h'F$ peak is above 400 km, the duration of spread F is only a few hours. Once the spread-F irregularities occur and there is no sustaining mechanism of the irregularities, these will decay in a time corresponding to the chemical loss time constant. To examine this on a quantitative basis, the chemical loss time constants are estimated corresponding to the average $h'F$ during 1900–2000, for the night of short duration spread F. For this estimation, the chemical loss coefficients given by Mitra¹² and

fluctuating east–west electric field forms one of the prerequisites of spread F generating and or sustaining mechanisms. This is consistent with the suggestion made by Hanson *et al.*¹⁴ that turbulent electric fields in the F region could be a necessary condition for equatorial spread F.

Short term relationships between solar flares, geomagnetic storms, and tropospheric vorticity patterns

It has been found that the 500–mbar vorticity area index (VAI), which is a rough measure of the strength of the cyclonic activity over the Northern Hemisphere, responds to solar flares in at least two ways. First, there is an increase in the VAI in the first two days after the flare. Then, after the geomagnetic storm which often follows a major solar flare, there is a sharp decrease in the VAI. The results are consistent with earlier studies of the development of pressure troughs in the North Pacific area.

Many investigators have reported short term relationships between variable solar activity and weather, but the relationships have often been unconnected and even contradictory. The results reported here seem to form a logical extension of other results recently reported^{1–4}.

Roberts and Olson⁴ verified an earlier finding regarding wintertime pressure troughs at the 300 mbar level, and their apparent response to a solar-geomagnetic signal. If a day of sudden increase in geomagnetic activity is called a geomagnetic key day and the day that a trough moves into or is formed in the Gulf of Alaska is called the 0-day of the trough, they verified that the following relationship held: troughs whose 0-days fell 2–4 d after a key day were selectively intensified, on the average, during the next few days. The day of maximum intensity was about 1 d after day 0, or about 4 d after the key day.

In this and all previous work, it was very crucial that 2–4 d must elapse between the key day and day 0 for the effect to be observed. If day 0 was less than 2 d after the key day, the intensification of the trough was, on the average, missing or even negative. The geomagnetic key day was defined as any day on which the planetary geomagnetic index, A_p , equalled 15 or more, and on which the one day increase in A_p from the previous day exceeded the monthly average A_p . Thus it was defined by the sharp front of an abrupt rise in geomagnetic activity.

To measure the size and intensity of the troughs, a VAI was devised. This is defined as the area over which the absolute

Table 1 Observed and estimated spread-F data

Date (1970)	Average height (km)	Chemical loss time constant (h) (calculated)	Duration of spread F (h) (observed)
February 26–27	355	2.8	2.0
March 30–31	350	2.5	1.75
April 18–19	315	1.9	1.1
May 15–16	345	2.2	2.2
June 13–14	305	0.75	1.0
August 19–20	290	0.5	2.0
September 19–20	370	4.4	2.0
October 29–30	330	1.3	2.5
November 25–26	335	1.7	2.3
December 18–19	335	1.7	2.3

CIRA 1965 model have been used. These are shown in Table 1 along with the observed duration of spread F. There is a fairly good agreement between the observed duration of spread F and the calculated chemical loss time constant. It should be noted that the duration of spread F depends on the initial strength of the irregularities as well as on the chemical loss time constant. Considering this, the agreement between the two is quite satisfactory.

The night-time $h'F$ fluctuations represent the true height (h) fluctuations corresponding to the undersurface of the F region¹³. The variation of $h'F$ (or equivalently of the true height h) with time represents the sum of the layer velocity and the apparent upward velocity caused by the chemical loss. The latter is not expected to show the type of fluctuations in $h'F$ observed in the present investigation (Fig. 1). As such, the observed fluctuations in $h'F$ should correspond to the true vertical motion of the F region, which at the Equator is attributed mainly to the electrodynamic drift caused by an east–west electric field. From this we contend that the $h'F$ fluctuations (observed on long duration spread-F nights) indicate similar fluctuations in the east–west electric field. We suggest that the

Fig. 1 Number of geomagnetic key days before and after zero days established by the three minimum value days per month of the 500 mbar VAI September–April, 1950–71.

vorticity exceeds certain threshold values. We have applied the same VAI definition to both 300 mbar and 500 mbar. We base the work in this paper on our 500-mbar results rather than those at 300 mbar, because the data at 500 mbar are more complete and homogeneous.

Wilcox *et al.*¹⁻³ have introduced a new solar signal into the study, namely the interplanetary magnetic sector boundaries that sweep past the Earth several times per month, apparently due to the Sun's rotation and the fact that they are imbedded in the solar wind and locked to magnetic field configurations on the solar surface. They also modified the VAI somewhat. Instead of matching VAI patterns with individual troughs, they integrated the VAI over the entire Northern Hemisphere north of 20°N. This makes the integrated VAI a completely objective parameter, whereas the VAI applied to individual troughs involves the degree of subjectivity necessary to identify specific troughs with vorticity maxima.

The Wilcox results, both at 500 and 300 mbar and with several independent data samples, showed a very consistent pattern. Approximately 1 d after the Earth intersects a solar sector boundary, the integrated VAI displays a 10% decrease. By 3–4 d after the crossing, the VAI has recovered to its original level or even beyond it.

Since there is a well known tendency for geomagnetic disturbances to occur near the time of sector boundary crossings, it was tempting to do a study similar to the Wilcox studies, but using geomagnetic key days as the solar signal. This report gives the results of such an experiment, plus a similar one in which major solar flare occurrence was used as the solar signal.

One of the difficulties in working with VAI data is that, although the VAI can be computed objectively by computer, the map sets needed as a basis for the calculations are somewhat non-homogeneous and therefore produce noisy data. Thus we decided in the first experiment not to use the VAI itself, but to select the three days per month when VAI was a minimum as the meteorological parameter. We then performed a superposed epoch analysis (SPE) of the number of geomagnetic key days preceding and following the three days of minimum vorticity.

The frequency of key days reaches a sharp maximum 1 d before the minimum vorticity (Fig. 1). The 1σ line on Fig. 1

was computed by the assumption of a Poisson distribution; it is the square root of the average number of key day occurrences so computed. Therefore, according to Langley⁶ the significance levels are conservative. By this estimate, the peak at day -1 is significant at almost the 1% level. Langley points out that "The Poisson answer is nearly always a shade weaker than the true binomial probability, so there is very little risk of getting a 'significant' answer when you shouldn't." It may be of interest that Langley also gives examples (ref. 6, pp. 249–250) of testing of similar distributions which give results much like ours. In addition the high value at day 0 is significant at better than the 5% level. It must be noted that not all 513 cases in the sample are independent—the days of minimum vorticity sometimes occur in clusters or even at times may be consecutive. But it is not certain that this detracts from the significance of the result. If the effect of a geomagnetic event is such that it causes several consecutive days to have low VAI values, this may support the reality of the effect.

The second part of the study involves a correlation between the occurrence and magnitude of major solar flares and the integrated VAI. Dodson and Hedeman⁵ have shown that, from a list of all well observed major flares, only the upper 20% or so in magnitude have a clear-cut causative relationship to magnetic storms. Thus in our study we used only the flares from the Dodson–Hedeman list having a combined index of 10 or more. This gave a list of 94 flares in the winter half year and 115 in the summer half, for the period 1955–1969 covered by the Dodson–Hedeman list. As a preliminary experiment we used the days of minimum vorticity, as in Fig. 1, to establish day 0, and performed an SPE analysis of flare index from day -30 to day 30.

The results (not shown here) showed only one peak, a highly significant increase in flare index at day -3. But this experiment did not add much to our knowledge, because of the well known relationship between major flares and geomagnetic disturbance. To show the relationship between solar flares and VAI in a more explicit way, we prepared Fig. 2. First, in order to remove the seasonal trend in the VAI, we subtracted each daily value from the 29-yr mean for that day. An alternative way of taking out the seasonal trend would be to subtract each daily value from a fairly extensive running mean value, for instance 27 d. We tried that technique, and again got results quite similar to those shown in Fig. 2. Even with this trend removal procedure, there is still considerable noise in the VAI data, as mentioned earlier. We performed an SPE analysis with the 0 dates determined by the occurrence of a solar flare of index 10 or more (roughly the upper 20% in flare magnitude). The VAI data appear in the form of 24-h changes, so that the data shown at the 0 point is the 24-h change in the integrated VAI from day 0 to day 1.

To test the statistical significance of the results we have plotted them in the form of Student's *t* values. The results are somewhat unexpected. In the winter half year, Fig. 2 shows a significant decrease in integrated VAI, from three to four days after the flare. This is just what we would expect, in view of Fig. 1 and the fact that these are the flares that typically produce geomagnetic storms about two to three days after the flare. But an even more significant increase in VAI occurs on the first and second day after the flare, a surprising result, since we had not seen evidence for this in other data. Although the noise level in Fig. 2 is high, we feel that both the sharp increase and the subsequent decrease in VAI are real. The increase seems significant on both days 1 and 2 following the flare. As in Fig. 1, we know of no way to incorporate the position of the peaks into a significance test. That is, if the most significant peaks and troughs occurred at day -18 or day 22, for instance, we would be hard pressed to ascribe a causative relationship to them. But since they occur near day 0, we feel that the suggestion of a physical connection must be taken seriously. The fact that a similar relationship (not shown) was found in independent data from summer months, even though it was weaker, must also be considered as evidence for the reality of the finding.

Fig. 2 Student's t values for 24-h change in Vorticity Area Index (expressed as departure from mean) before and after 94 large flares, 1955–69 (winter season, October–March). Arrows on right indicate labelled confidence limits.

From this work it is possible to suggest an average sequence of events, as follows (applicable primarily, but by no means exclusively, to the upper troposphere and to the winter half year). Starting with the day of a large solar flare as day 0:

- (1) By day 1 or 2, the Northern Hemisphere VAI increases sharply, by 5–10% above its background value;
- (2) by day 2 or 3, a geomagnetic storm has started, which may persist for several days;
- (3) by day 3 or 4, the VAI has decreased to a value 5–10% below its level before the flare;
- (4) by day 5 or 6, the VAI has recovered back to its original level.

The results of Fig. 2 can also be used to suggest a reason for the trough intensification in a large homogeneous area like the North Pacific following a geomagnetic key day. Immediately following the geomagnetic key day the integrated VAI is depressed. It is generally found that troughs in the North Pacific reflect the general hemispheric situation—they tend to be smaller when the integrated VAI is small. By 3 d after the key day, the hemispheric VAI is increasing, and the Pacific troughs apparently share in this tendency.

These results, of course, are true only in the average, and should not be taken to be case studies. Moreover several additional refinements suggest themselves. For instance, we should examine the position of the flare on the disk of the Sun as a factor in determining the VAI response. It is undoubtedly important, and the type of response obtained may give a clue as to what parameter in solar activity is most important, the ultraviolet or X-ray flux, particles, and so on. It will also be vital to examine the geographic areas of greatest response. Answers to questions like these will aid greatly in the all important problem of discovering physical mechanisms to explain the observed results. Once we have reasonably acceptable physical models, we should be enabled to perform much more critical tests of the reality of solar-weather interactions.

Crystal structures, the Earth and Dirac's Large Numbers Hypothesis

DIRAC's Large Numbers Hypothesis assumes that the large, dimensionless numbers obtained from the ratios between fundamental physical constants are related to the age, t , of the Universe^{1–4}. The theory demands two important consequences: that matter be continuously created with time and that the gravitational constant, G , vary with time. To reconcile those demands with Einstein's theory of gravitation two metrics are required. One, the Einstein metric, involves the equations of motion and classical mechanics; the other, the atomic metric, refers to quantum mechanics and laboratory measurements of distances and time as determined by atoms. According to Dirac, the continuous creation of mass requires either of two models—one, called additive creation, assumes that matter is created uniformly throughout space (mostly intergalactic space). The other model is called multiplicative creation. It calls for the creation of matter where matter already exists in proportion to the amount and kind already existing.

A corollary of the multiplicative creation model is that Einstein's cylindrical closed Universe suit cosmological considerations. Adopting the Einstein metric, and using the Einstein field equations, Dirac argues that if the radius of the Universe and G were constant and the galaxies were not receding then all atomic distances, expressed in Einstein units, would vary proportionally to t^{-1} . In terms of Einstein units, the number of atomic particles varies as t^2 whereas the mass of atomic particles varies as t^{-2} . In that way the mass of a classical body can remain constant. The fundamental atomic constants of physics all vary in a compensatory fashion, so, presumably, as 'new' atoms are added to 'old' atoms all atoms are changing so that at any point in time 'old' and 'new' atoms are indistinguishable.

Suggested tests of the theory³ remain unconfirmed. Measurements of astronomical distances with atomic apparatus could provide a test as could highly accurate, secular measurements of G . The Earth can also provide tests for the theory. Adopting the atomic metric, mass and atomic distances remain constant, but as G varies the Earth would expand and move away from the Sun^{1,5,6}. Continental drift and plate tectonics are, in part, consistent with this test of the atomic metric.

Crystals in rocks of the Earth represent a record of possible change from at least 3×10^9 years ago up to the present so their atomic structures should agree with the predictions of the theory. When dealing with atomic units no problem emerges as mass and atomic distance remain constant so no differences between old and new crystals can be expected since any variation in G would be negligible compared with the atomic forces involved. But when dealing with Einstein units major changes are demanded at the atomic level. Dirac² has stated that "There might be some difficulty in understanding how the matter in very old rocks can have multiplied without disrupting their crystal structure". If atomic distances vary as t^{-1} then the d -spacings in crystal lattices in geologically older minerals should

be observably different from those in the same minerals forming today. The geological evidence, however, is strongly against such a prediction: the lattice dimensions of a 3×10^9 yr-old quartz crystal are the same as the lattice dimensions of quartz grown in the laboratory. Indeed, the molecular weight and the X-ray density of the unit cells are the same. Therefore, unless Avogadro's hypothesis is violated, the number of atoms in the unit cell is also the same. The relevant equation from X-ray crystallography is:

$$V = Mn/\rho N_0 \quad (1)$$

where, respectively, V is the lattice volume, n is the number of atoms, M is the molecular weight, ρ is the X-ray density of the crystal unit cell, and N_0 is Avogadro's number. The equation must be valid in both atomic units and Einstein units. But no difference in any of these parameters is observable between an early Precambrian crystal and a modern crystal of the same composition. Therefore, in Einstein units, this condition violates the predictions of the multiplicative creation model.

Gittus⁸ has offered an apparent solution to this difficulty and has suggested that the 'new' atoms could occupy interstitial positions at vacancies and dislocations. Calculations show that for a crystal 3×10^9 yr old, if $n \propto t^2$ more than 30% of the atoms would have to occupy interstitial positions. Although this is clearly too many for any crystal to accept without lattice disruption it would, in any case, have to produce a marked difference between the X-ray and pycnometrically determined densities.

The geological evidence does not confirm the predictions of the multiplicative creation model and unless Avogadro's number is to be held constant with time, similar difficulties arise for the additive creation model. In its present form, therefore, the Large Numbers Hypothesis seems to be unacceptable.

I thank R. F. Fudali for discussion and comments.

Origin of alkaline rocks

THE hypothesis of limestone assimilation^{1,2}, developed to explain differentiation of the Vesuvius magma, was long unchallenged for that area—and extended³—even when it had to be abandoned for other alkaline provinces. Trace element data made it difficult to reconcile the limestone assimilation hypothesis with many observations⁴⁻⁷, but even in 1966 when Hurley *et al.*⁵ challenged Rittmann's hypothesis¹ (on the basis of Sr isotope data) they had insufficient evidence to rule it out. But Pb isotope data support⁶ the genetic model of Hurley *et al.*⁵, and further evidence against Rittmann's hypothesis is presented here.

The main difficulty Hurley *et al.* encountered results from the overlap of the $^{87}\text{Sr}/^{86}\text{Sr}$ values found in limestone and in the alkaline rocks from Vesuvius and the other volcanic areas they investigated. The Sr isotopic composition of limestone is determined by two components: The Sr in the carbonate will have the isotopic composition of seawater at the time of deposition, assuming no later Sr exchange. Clay minerals in the limestone will generally have retained their inherited isotopic composition. Peterman *et al.*⁹ found a range in the $^{87}\text{Sr}/^{86}\text{Sr}$ ratio for seawater of 0.707–0.709 with the least radiogenic Sr

Fig. 1 The change in the Sr isotopic composition which would be produced by the assimilation of limestone with 610 p.p.m. Sr (average limestone¹⁴) or evaporites with 4,000 p.p.m. Sr (possible, though rather high value¹⁶) is plotted as percentage of assimilated sediment. The magma is assumed to have 550 p.p.m. Sr and an isotopic composition similar to the rocks from Vulture. The Sr isotopic composition of the sediments is assumed to be equal to Miocene seawater⁹. The data from Vulture are taken from ref. 8.

in the Jurassic and Cretaceous and a rapid increase in the ratio during the Tertiary. These will be minimum values. Impure limestone tends to have higher values due to inherited radiogenic Sr in the clay minerals. For example, average values of 0.7129 and 0.7141 for Jurassic and Cretaceous limestones were obtained¹⁰ as compared with 0.707 for pure limestone of the same ages. Impure limestone will have less radiogenic Sr than pure limestone only in the rare cases when a significant amount of the total Sr originates from volcanic material with non-radiogenic Sr derived from the mantle. Thus, an attempt to refute the limestone assimilation hypothesis will be facilitated, if the uncontaminated magma has a $^{87}\text{Sr}/^{86}\text{Sr}$ ratio below the minimum value for seawater. New Sr isotope determinations on the Italian alkaline rocks⁸ have shown that this seems to be the case for the Cainozoic¹¹ volcanic complex of Mt Vulture in Southern Italy. The assimilation of limestone¹² or Miocene evaporites¹³ has been suggested as an explanation for the occurrence of haüyne and leucite in rocks from Mt Vulture.

Assuming Sr concentrations for the uncontaminated magma and the sediment, the effect on the isotopic composition resulting from these hypotheses is demonstrated in Fig. 1. None of the predicted correlations can be observed. The range in the $^{87}\text{Sr}/^{86}\text{Sr}$ ratio is very small and the mugearite (VULT-2), which according to the hypothesis should have suffered little or no contamination, has in fact a ratio which is slightly higher than the rest of the samples. Furthermore, the haüynofyr (VU-342), which according to the hypothesis should have the highest portion of assimilated sediments, has the lowest isotope ratio, which is in contradiction to the hypothesis. Thus, a characteristic feature of these rocks—the very high Sr concentrations—cannot have been caused by the assimilation of a sediment.

As more Sr isotope data on the Italian alkaline rocks become known, a pattern emerges, which enables one to test Rittmann's hypothesis also at Vesuvius. The Sr isotope ratio is rather constant throughout the eruption sequence for each volcanic centre (with a total range generally less than 0.0012) and each centre has a distinct range. This indicates individual and quite uniform sources. The Somma-Vesuvius volcano seems to be the one exception. Here relatively large variations in $^{87}\text{Sr}/^{86}\text{Sr}$ which ranges from 0.7068 to 0.7100, are found. Even within the same lava flow almost the same spread can be observed: two samples from the 1944 lava flow yield 0.7072 (ref. 8) and 0.7095 (ref. 10). These exceptional large variations and the inhomogeneities within a single lava flow point to a superficial contamination with Sr. This might well be caused by the abundant

limestone inclusions which are subjected to various degrees of metamorphic alteration¹. But if Rittmann's hypothesis were correct, that increasing assimilation with time of dolomite and limestone would have produced the successive desilification of the Vesuvian lavas, the Sr isotopic composition would be expected to correlate with the eruption sequence and the silica content. Neither can be observed.

This line of argument only breaks down if the exceptionally large variations are not caused by superficial contamination, or the contamination has a different origin, for which no evidence has yet been put forward. Then any Sr contribution from the limestone inclusions would be masked and the Sr tracer method could not be used to detect any possible limestone assimilation at Vesuvius.

Laboratory-induced self reversal of thermoremanent magnetisation in pillow basalts

CONSIDERABLE attention has been paid to the changes in the magnetic properties of pillow lavas with distance from a ridge¹. It has been found^{2,3} that the originally stoichiometric titanomagnetites are altered at sea-floor temperatures to cation-deficient titanomagnetites (titanomaghaemites). The degree of cation deficiency—the fraction of initial Fe^{2+} oxidised to Fe^{3+} —is described by the parameter 'z' (ref. 4). As the titanomaghaemite evolves, all the magnetic properties (for example, Curie point, saturation magnetisation, coercive force) change, but though the changes cause a decrease in the intensity of magnetisation, the direction is preserved.

We have attempted to duplicate the process of oxidation in the laboratory. In our experiments thin disks (2.5 cm in diameter, by 1.5 mm thick) of basalt were cut from cores drilled into the pillows. Each slice was progressively demagnetised in an alternating field up to a peak of 1,000 oersted. Next, the sample was kept in a field 1.0 of gauss at 150 °C in water at typical sea-floor pressures (~0.5 kbar) for a length of time, then cooled to room temperature in the 1.0 gauss field, and finally the thermoremanent magnetisation (TRM) was demagnetised in an alternating field (a.f.). This cycle was repeated with increasing time intervals until over 3,000 h at 150 °C had been accumulated. Two experiments were carried out on pillows dredged from the Median Valley of the Mid-Atlantic Ridge at 45 °N.

The radial variation of the composition of the titanomagnetites was measured³. By taking the lowest Curie temperature phase as stoichiometric titanomagnetite an x-value of 0.6 is obtained. If it is assumed that x remains constant throughout, then z can be obtained from the Curie temperature.

The a.f. demagnetisation curves for the partial thermal remanences (PTRMs) acquired by the first sample (56-3-35—the 35 indicating a sample 35 mm from the pillow rim), which had

Fig. 1 Alternating field demagnetisation curves for successive PTRMs acquired by sample 56-3-35 on cooling from 150 °C in a 1.0-oersted field. Cumulative times at 150 °C: a, 46 h; b, 174 h; c, 1,070 h; d, 3,545 h; e, 588 h; f, 3,370 h; g, 3,110 h.

an initial $z \approx 0.35$, are shown in Fig. 1. First there was a long interval during which PTRM acquisition slowly decreased with a corresponding slight increase in hardness, seen by normalising the curves. Next the sample started to acquire a component of remanence anti parallel to the external field, until after 3,110 h it had reversed completely. After further heating the PTRM reverted to normal and became indistinguishable from PTRM acquired at much shorter times. This sort of transient self reversal is similar to that described by Ozima and Ozima⁵.

In the second experiment one sample showed complete self reversal; two showed very small reverse components and two showed no reversal at all. The a.f. demagnetisations of the PTRMs for the self-reversed sample (197-8-45), with initial value of $z \approx 0.15$, are shown in Fig. 2. The final curve in this case clearly represents an intermediate state between the 1,070 and 3,110 h states for sample 56-3-35. Curie point measurements at successive stages of alteration for this sample showed an increase in 'z' to about 0.7 followed by splitting of the cation-deficient titanomagnetite so that a higher Curie point (~450 °C) phase is identifiable as well as a phase with the initial Curie point. Self reversal can be shown to accompany the phase splitting in some samples. An attempt to speed the reaction by heating at 210 °C caused phase splitting but no self reversal.

We suggest that the self reversal is caused by an interaction between the titanium-poor daughter phase with the Curie point at 450 °C and the original titanomagnetite. Domains of daughter phase will acquire a chemical remanent magnetisation (CRM) parallel to the external field as they exsolve from the parent. This will occur as they grow in size during the time spent at 150 °C, increasing their relaxation time, until they are normally magnetised, stable, single domains⁶. On cooling, the previously a.f. demagnetised, mother phase will be subjected to both the external field and an interaction field from the daughter phase with which it is in contact. It is conceivable that the interaction field will dominate and thus the mother phase will acquire a reverse PTRM. It is possible that the reverse PTRM of the mother phase will cause a net reverse moment in the sample^{6,7}.

It is not possible to decide definitely whether this is a magnetostatic or an exchange interaction. Experiments with stronger

Fig. 2 Alternating field demagnetisation curves for successive PTRMs acquired by sample 197-8-45 on cooling from 150 °C in a 1.0-oersted field. Cumulative times at 150 °C: a, 82 h; b, 166 h; c, 622 h; d, 2,351 h; e, 3,023 h.

fields may be able to resolve this question. The reverse PTRMs are, however, softer (mean demagnetisation field = 80 oersted; compare with 200 oersted; MDF = 80 oersted; compare with 140 oersted for the two samples) than the normal PTRMs. It has been found^{8,9} that the reverse TRM caused by exchange interaction is harder than the normal TRM, so perhaps the present case is an example of magnetostatic interaction.

An important question is whether we should anticipate self-reversed basalts in the ocean crust. In nature the daughter regions could acquire a reverse CRM as they are exsolved in the interaction field of the mother regions. A necessary condition for self reversal is the splitting of the original titanomagnetite into two or more phases. During the phase splitting, conditions exist which may lead to self reversal. Phase splitting of titanomagnetites caused by oxidation on the sea floor at very low temperatures has not been observed. It is, however, well known from laboratory¹⁰ and field studies¹¹ that alteration at 100 °C to 150 °C causes phase splitting in basaltic titanomagnetites.

These experiments suggest that though self-reversed rocks may not be found on the sea floor, they may occur wherever the temperature has been sufficiently raised to split the cation-deficient titanomagnetite into two or more phases, perhaps at depth in the oceanic crust and perhaps in continental regions of hydrothermal alteration.

Sliding friction of rubber

WE report experiments demonstrating that it is possible to predict quantitatively the level of friction arising when a smooth rubber sphere slides on glass. Analysis of the sliding friction is based on a surface energy approach. Observations show that when a smooth rubber surface advances over glass by a continuous peel process (Schallamach waves) the work done in the region of contact can be calculated in terms of a rate-dependent surface energy and thus an expression found for the tangential frictional stress required to maintain uniform relative motion between the surfaces. In some cases predicted and observed frictional stresses agree to within 10%.

Schallamach observed¹ that for sliding of soft rubber spheres on hard tracks relative motion between them was often only due to "waves of detachment" crossing the region

Fig. 1 Generation of Schallamach waves at rubber-track interface $F = \gamma\omega/\lambda V$.

of contact. Between these waves there was strong adhesion. The waves moved as folds in the rubber surface and all gross displacement seemed to be solely associated with them. More recent observations² have revealed some conditions for their appearance. The waves have been thought to originate from elastic^{2,3} or viscoelastic² instability due to tangential stresses in the contact region, so causing the rubber surface to buckle. Before the rubber surface can buckle to form a wave, however, it must first be unpeeled from the hard track⁴. To unpeel smooth soft rubber from glass requires considerable energy^{4,5} and the process is greatly influenced by the viscoelastic behaviour of the rubber^{6,7}. There is evidence that the apparent surface energy required to peel apart these surfaces is of the form $\gamma = \gamma_0 f$ (hysteresis) where γ_0 is the equilibrium energy associated

Fig. 2 Apparatus to investigate the role of Schallamach waves in sliding rubber friction. The glass plate is a prism beamsplitter designed for viewing the contact region between rubber and glass in high optical contrast⁸. Rubber hemispheres of various vulcanisates were moulded to give an optically smooth surface¹⁰ of radius 1.85 cm. A variable speed electric motor drove a traverse to move a hemisphere back and forth (\odot/\otimes perpendicular to plane of paper) under the glass plate.

Table 1 Wave observations and the friction of rubber hemispheres on glass

Rubber vulcanisate (Hardness IRHD)	Body velocity V ($\mu\text{m s}^{-1}$)	Centre of contact observations			Frictional stress (MPa)		
		ω (mm s^{-1})	λ (mm)	γ (J m^{-2})	Central	Theory Integrated	Observed
Natural rubber							
peroxide cure (35)	590	17.4 ± 4	1.3 ± 0.2	5.98	0.14	0.16 ± 0.03	0.15 ± 0.02
sulphur cure (44)	240	5.9 ± 0.6	0.34 ± 0.1	5.01	0.36	0.53 ± 0.015	0.48 ± 0.04

Styrenebutadiene (50)	110	2.9 ± 0.3	0.52 ± 0.08	9.12	0.46	0.44 ± 0.02	0.45 ± 0.03
Butyl rubber (34)	50	0.59 ± 0.06	1.2 ± 0.2	15.1	0.15	0.16 ± 0.03	0.20 ± 0.03
Polybutadiene (53)	110	4.0 ± 0.8	0.34 ± 0.08	1.78	0.19	0.20 ± 0.03	0.26 ± 0.03
Acrylonitrilebutadiene (43)	30	0.70 ± 0.2	0.6 ± 0.1	5.76	0.22	0.22 ± 0.06	0.29 ± 0.02

with the change in interfacial area and where the function of hysteresis may be up to 10^4 in magnitude⁸. Thus the question arose as to whether the unpeeling of rubber from the track was the main origin of the frictional work that is done in sliding the sample⁴.

The idea of a rate-dependent surface energy has been applied to Schallamach waves in the following way⁴. Consider a rubber slab pulled at a velocity V over a hard track by a tangential stress F (Fig. 1). The waves move with a velocity ω and their spacing apart is λ . If γ is the rate-dependent surface energy per unit area required to peel the rubber from the track and if the energy dissipation in the bulk of the rubber is neglected, then in steady-state sliding where the elastic energy of the rubber is not varying the loss of energy is solely associated with the

peeling. In time dt the stress F does work $FVdt$ per unit area and the energy lost by waves is $(\gamma\omega/\lambda)dt$. Equating these gives

$$F = \gamma\omega/\lambda V \quad (1)$$

Some energy is returned each time surfaces readhere in the wake of a Schallamach wave, but this is negligible⁴ compared to that lost in peeling. The validity of equation (1) was assessed approximately by using the published wave observations of others^{1,2} together with estimates of γ at the relevant rates of peeling ω and it has been shown⁴ to predict the correct order of magnitude for the sliding frictional force of a smooth rubber contact.

To investigate more directly the relation between surface energy and rubber sliding friction we have constructed apparatus to measure simultaneously frictional stress, wave velocity and wave spacing for the sliding at uniform velocity of a smooth spherical rubber surface over a polished glass plate (Fig. 2). The plate normally loaded on the rubber was attached to a supporting spring, tangential deflections of which gave a measure of the frictional force between the sliding surfaces. The sliding contact area was viewed through a low power microscope and by using a double light flash technique it was possible from a single photograph to deduce the wave velocity ω and spacing λ (Fig. 3). Any wave passing through the contact was photographed twice and from the displacement, knowing the time interval between flashes, its velocity ω could be found. Measurement of the distance between waves of the same flash set gives λ . The surface energy γ is rate dependent and was determined from independent sets of experiments; measurement of the contact radius between a smooth sphere of rubber and a glass plate with no applied load yielded a value for the surface energy required to separate the surfaces¹¹, the rate at which the surfaces were separated determined the magnitude of γ for a particular vulcanisate⁴. Thus for a range of vulcanisates rate-dependent γ values were found. At the peel rates set by the Schallamach waves, γ values are as much as two or three orders of magnitude greater than the equilibrium surface energy γ_0 generally found for hydrocarbon surfaces.

The experimental observations are shown in Table 1. If average values of ω and λ are taken midway across the contact, agreement between theory and experiment is good. The Schallamach waves, however, do not travel at a uniform velocity². From photographs such as Fig. 3, it was possible to measure accurately the variation in velocity ω and spacing λ of the waves as they crossed the contact area. Point values of the frictional stress F were calculated using equation (1) and then summed across the contact to arrive at a more accurate theoretical value of the total frictional stress. In some cases the integrated theoretical frictional stress is within 10% of the direct observations (Table 1).

Thus it seems that for a wide range of vulcanisates, at least in the case of smooth surfaces, surface energy of peeling probably has a central role in the frictional behaviour of rubber. Furthermore, this picture gives a ready mechanism for the known viscoelastic behaviour of rubber friction because the peeling process has already been established as being viscoelastic in character. This is believed to be the first time such an

Fig. 3 Typical double flash photograph of Schallamach waves for natural rubber. The duration of each flash was $1/1,200$ s and the interval between flashes could be varied between $1/100$ s up to 1 s using a simple delay system. To distinguish clearly between each set of waves one light flash was arranged to be slightly less intense than the other so that on a black and white photograph one wave set appears darker than the other. The major axis diameter of the elliptical contact area in this photograph was 3.2 mm at a sliding velocity of $570 \mu\text{m s}^{-1}$ under a normal load of 0.085 kg.

approach has been taken to provide a quantitative description of rubber friction based on independently measurable physical quantities. Such a picture avoids having to invoke any specific structure or molecular jump theory.

Relaxation of the Bernal model

RANDOM packings of spheres serve as models for a variety of noncrystalline particulate and molecular aggregates, some of which, for example the amorphous phases of metals and alloys, offer abundant possibilities for the comparison of theory and experiment^{1–4}. Nevertheless there remain significant discrepancies between the measured structural characteristics of real systems and the geometrical models considered by Bernal⁵, Cohen and Turnbull⁶ and others to be prototypes for the simple vitreous state. The most enduring of these is perhaps the difference in position and intensity between the two components of the split second peak in the radial distribution function observed in actual and artificial systems^{2–4}. Attempts to remove this disagreement by variation of the algorithm used in computer-simulated packings have only been partially successful. In particular Sadoc *et al.*² have noted that it is relatively easy to build in strong local density inhomogeneities associated with icosahedral arrangements^{7,8} and Connell has experimented with the packing of compressible spheres, showing that significant shifts in the radial distribution function result from the softening of the interatomic potential⁹.

We thought it worthwhile to 'relax' the '1968' (ref. 10) Bernal sphere-packing model under a realistic interatomic potential function to observe which of the resultant geometrical changes can occur fairly easily in an initially dense packing, as distinct

Table 1 Frequency of polyhedron types

	Hard sphere	Relaxed	Crystal close to melting point†
'Crystalline'			
(0 3 6)*	0.32	0.34	0.40
(0 4 4)	0.22	0.27	0.44
(0 5 2)	0.06	0.03	0.07
	0.60	0.64	0.91
'Non-crystalline'			
(0 0 12)	0.02	0.04	<0.01
(0 1 10)	0.08	0.11	0.01
(0 2 8)	0.14	0.17	0.06
	0.24	0.32	0.07

Only clearly significant types are shown. Hence the proportions given do not total to unity.

*The polyhedron type ($n_3 n_4 n_5$) is characterised by n_3 , n_4 , n_5 faces with three, four and five edges, respectively.

†This column refers to a Monte Carlo simulation of crystalline argon at 84 K using a Lennard-Jones potential function¹⁰.

from those which may need to be induced in the building process. We used quite standard computational techniques for the 'optimisation' of many-variable potential functions¹¹, applying a Lennard-Jones 6:12 potential between all atoms present and allowing the program to seek out a natural potential energy minimum in the neighbourhood of the initial 'Bernal' configuration. Even with the best programs available, however, we could not have hoped to handle the whole 7,934-atom Bernal packing and so were obliged to extract a central core of some 999 atoms for the calculation.

The algorithm used was based on a version of the Fletcher-Reeves conjugate-gradient method¹², supplied to us by the Theoretical Physics Division, AERE, Harwell, and run on the London University CDC 7600 machine. We took precautions to see that the program searched thoroughly in the near vicinity of the original point in configuration space, avoiding as far as possible the unnatural rearrangement of atomic positions which might have occurred with a 'dynamic' optimisation method. Nevertheless, the final configuration obtained cannot be expected to be in any way unique and there will undoubtedly be a multitude of alternative minima at similar or smaller distances, from the 'Bernal' point on our 2,991-dimensional energy surface. We assume only that the short-range geometrical correlations at the minimum found shall be statistically representative of the whole class of alternatives which might be discovered by repeated excursions in the neighbourhood of the 'Bernal' configuration.

Fig. 1 The Bernal model before (a) and after (b) relaxation under the Lennard-Jones potential. Only the 100-atom core of the 999-atom assembly is depicted. Atoms within a distance $\sqrt{2}$ of each other are shown bonded. The radius of the spheres is drawn at 0.15 of the diatomic equilibrium distance.

Fig. 2 Radial distribution function for the relaxed and unrelaxed Bernal model. The histogram for the original system (shaded) is superimposed on that for the relaxed (blank). Distance in terms of the Lennard-Jones pair distance. Vertical scale in arbitrary units.

The results of this exercise can be presented in various ways. Fig. 1 shows computer-generated drawings of the central core of 100 atoms extracted from the 999-atom aggregate before and after relaxation. We were able to scrutinise many such drawings at different angles and in stereoscopic form to confirm the impression given by the figure that perceptible changes have taken place in the spatial relationship of neighbouring atoms even though, for the most part, the topology of nearest-neighbour connections is relatively undisturbed.

The resulting structural changes in fact gave rise to a corresponding decrease in total potential energy of some 5.1% from the Bernal configuration. This, we estimate, would have decreased further by some 0.3% had we continued computing for quite unjustified times. The r.m.s. distance moved by the spheres was also monitored and amounted to approximately one-fifth of the nearest-neighbour distance averaged over the whole assembly. Detailed examination of the coordinates showed that a disproportionate contribution to this figure came from atoms at or near the surface of the model which underwent relatively large adjustments.

Figure 2 shows the averaged radial distribution function of the 999-atom model before and after relaxation, computed using the Mason correction¹³. As expected, the first peak becomes less sharp while the first minimum is deepened. More significantly, the two components of the split second peak reverse in intensity in precisely the manner observed in amorphous Ni-P and other disordered alloys²⁻⁴. There is also a suggestion of a splitting in the smaller third peak. Otherwise the radial distribution function is unexceptional and the peak positions, which in general can be expected to depend somewhat on the nature of the potential, remain virtually unchanged for the Lennard-Jones case.

A more sensitive indication of the changes in local structure is to be found in the statistics of the Voronoi polyhedra¹⁵ before and after relaxation. Table 1 shows the frequency of some particularly significant polyhedron types for the random packing before and after relaxation, in comparison with those for the crystal near the melting point. There are significant changes in the statistics of faces per polyhedron which together lead to a reduction in the average number of faces \bar{N} from 14.20 in the Bernal configuration to some 13.99 in the relaxed form. (Compare values of 14.46 and 14.07 for Lennard-Jones liquid and solid phases, respectively, at the melting point¹⁰.) On more detailed analysis we observed the following:

- (1) The size distribution of normalised polyhedron volumes V_1/\bar{V} indicating the variation of local volumes effectively occupied by atoms shows relatively slight adjustment on relaxation. A slight downward shift in the maximum is observed with only small change in standard deviation (0.039 and 0.037, respectively, before and after). This indicates that the overall volume decrease in the packing goes with a redistribution of local volumes rather than simply a rescaling.
- (2) The frequency of the five-edge faces increases at the expense of others, particularly the three- and seven-face components, but otherwise the qualitative difference between 'random' and 'crystalline' polyhedron statistics is maintained (Fig. 3).
- (3) On analysing the statistics of occurrence of actual polyhedron types rather than of faces, significant trends may be distinguished. Thus the occurrence of the (0 0 12) polyhedron, indicative of distorted icosahedral arrangements, shows an appreciable increase in the relaxed array (Table 1). This trend is also shared by the (0 1 10) and (0 2 8) types which also arise from the distorted icosahedron. Crystallisation must result in a large increase in the occurrence of (0 4 4) and (0 3 6) types; these contribute little in the original packing and show no particular increase in relaxation.

The most striking single feature of these results is undoubtedly the fall in the average face-count \bar{N} on relaxation. In view of (1) to (3) and the lack of any visual evidence in the drawings, this cannot be attributed to incipient crystallisation and we conclude that we have observed a spontaneous reinforcement of locally 'tetrahedral' order⁹⁻¹¹, perhaps occasioned by the formation of distorted motifs related to the 13-atom icosahedron. That these do not seem to have occurred on the scale predicted in the experiments of Sadoc *et al.* is not surprising in as much as we have taken as our initial configuration the particularly dense arrangement based on the Bernal ball-bearing model. Even with the soft potential used, this may have introduced unnatural constraints, with atoms 'jammed' and unable to take up more efficient minimum configurations without passing by way of complicated high-dimensional saddle points that are inaccessible with the program used.

How worthwhile it may be to elaborate further packing structures without reference to the physical deposition process

Fig. 3 Comparison of the Voronoi polyhedron face-frequency for: a, the relaxed Bernal model; b, the hard-sphere Bernal model; c, the Lennard-Jones crystal at melting point.

it is desired to model seems debatable. There may simply not be a single canonical structure appropriate to vitreous packings generated in unspecified experimental conditions. In any case it seems necessary to assert that, in view of the above results, the Bernal-Cohen-Turnbull view of the random close-packed structure as one essentially determined by hard-sphere repulsions and a particular, limited set of basic polyhedral relationships may need refinement when applied to the aggregation of real atoms under definite thermodynamic and mechanical constraints.

We thank the Science Research Council for partial support of this work and the Theoretical Physics Division, AERE, Harwell, for supplying computer programs. Stereo reproductions of Fig. 1 and other drawings will be supplied by the authors on request.

Examination of ancient pottery using the scanning electron microscope

A SEQUENCE of pottery sherds from Iraq spanning the period about 6000 BC to 750 AD and two sherds from Turkey about 5000 BC have been examined using a scanning electron microscope (SEM). This examination provided information on the internal morphology developed during firing and in particular information on the extent of vitrification (the glassy phase) and the pore structure^{1,2}. The extent of vitrification provided a useful parameter for characterising the quality of the pottery since it influences several physical properties (such as, hardness, strength, permeability) which are relevant to its suitability for the various uses to which it might be put. In addition by refiring samples of the pottery at known temperatures and determining, by re-examination with the SEM, the temperature at which an increase in the vitrification had occurred, it was possible to estimate the firing temperature used in antiquity.

Fresh fracture surfaces in the pottery, coated with a thin layer of Au-Pd, were examined in a SEM (Cambridge S600) both before and after refiring at known temperatures in the range 750 to 1,250 °C. The refirings were carried out in a tubular furnace in air at a heating rate of 200 °C h⁻¹ with a soaking time of 1 h at the peak temperature.

The nature of the internal morphology observed with the SEM together with X-ray powder diffraction data established that all the pottery was manufactured from calcareous clays. On the basis of the stage which had been reached in the progressive development of vitrification, it was possible to divide the pottery into four groups (Table 1). The first group (NV) contains pottery in which there is no vitrification and the

Fig. 1 Scanning electron micrograph of extensively vitrified pottery sherd (V) from Nineveh (Neo-Assyrian), Iraq. Bar represents 10 µm.

aggregates of flaky clay particles are essentially the same as in raw clay. The second group (V) exhibits extensive vitrification with a network of smooth-surfaced glass filaments forming an open or cellular structure over the fracture surface (Fig. 1). In the third group (V+), the cellular structure has begun to coarsen and larger areas of glass are present. Finally the fourth group (TV) exhibits total vitrification, the cellular structure having disappeared and been replaced by a continuous vitrified surface containing isolated pores (Fig. 2).

By means of refiring experiments on the pottery, together with the data obtained from examining specimens of calcareous clays fired at known temperatures and showing a similar pattern of vitrification development, it was possible to assign approximate firing temperature ranges to the various vitrification stages as indicated in Table 1. In assigning these ranges, it was assumed that the firing times (heating plus soaking time) employed in manufacture were comparable with those employed during refiring. Significantly faster heating rates (say 800 °C h⁻¹) and shorter soaking times (5 min) would have required firing temperatures higher by about 50 °C to achieve the same extent of vitrification. Second, on the basis of the colour of the pottery, it was assumed that it had been fired in an oxidising atmosphere. If fired in a reducing atmosphere, firing temperatures lower by about 50 °C would have produced an equivalent vitrification.

The pottery from Iraq was all fired to sufficiently high temperatures to produce, at least, extensive vitrification (V)

*Type-site given in brackets where this differs from provenance. Except for Hacilar, which is in Turkey, all the sites are in Iraq.

and for most of the periods under consideration, this group predominates (Table 1). The principal exception is the Ubaid pottery which exhibits chiefly total vitrification (V+ and TV), indicating that consistently higher firing temperatures were employed during this period. It is therefore apparent that the technology required to manufacture extensively vitrified pottery using calcareous clays was developed in Iraq at a very early stage in the production of pottery and that this tradition in ceramic technology remained essentially unchanged over a 6,000-yr period. Furthermore the tradition in Iraq contrasts with that in Turkey during the period around 5000 BC where, although calcareous clays were again used, the firing temperatures employed were significantly lower and the pottery produced exhibits no vitrification (NV).

The use of calcareous clays, although obviously determined in part by their availability, is of interest since this type of clay possesses distinctive vitrification properties which facilitate firing². First, extensive vitrification (V) can be achieved at the comparatively low firing temperature of about 850 °C. Second, the characteristic cellular structure associated with extensive vitrification remains essentially unchanged over a temperature range of about 200 °C (from 850 to 1,050 °C) and therefore the control of the temperature attained during firing is not particularly critical. This contrasts with the situation for non-calcareous clays where the extent of vitrification increases progressively with increasing temperature so that the quality of the pottery produced can vary quite considerably with changes in firing temperature of about 50 °C. But in the context of estimating the firing temperatures employed in antiquity, the thermally stable structure associated with calcareous clays results in a wide temperature range being assigned to the extensive vitrification group (V) in Table 1.

These results establish that, because information is obtained on both the extent of vitrification and the firing temperature, the examination of ancient pottery with an SEM is valuable for characterising and distinguishing between the different traditions in ceramic technology in antiquity. Since the firing temperature required to produce a particular degree of vitrification can vary by as much as 200 °C, depending on the refractoriness of the clay and the firing atmosphere used, either the extent of vitrification or the firing temperature by itself does not fully characterise the ceramic technology. For example, the same extent of vitrification can be achieved by firing a calcareous clay at a low temperature (850 °C) or a refractory non-calcareous clay at a higher temperature (950–1,000 °C). Taken together, however, the extent of vitrification and the firing temperature reflect the technological capabilities of the ancient potters with respect to both their ability to achieve the necessary temperatures and their understanding of the refractory properties of the clay used. In this respect, therefore, the examination of ancient pottery with an SEM is more valuable than an estimate of the firing temperature by itself,

such as can be obtained either by studying those minerals altered during firing^{3,4} or by thermal expansion measurements⁵.

We thank Dr P. R. S. Moorey of the Ashmolean Museum, Oxford, for providing the pottery sherds.

Temperature-independent relaxation in a lamellar block copolymer

It has long been assumed that all processes giving rise to stress relaxation in high polymers are very dependent on temperature. The peak in mechanical or dielectric loss factor ($\tan\delta$) can be used to characterise the most probable relaxation time of a high polymer solid. The temperature locus of this relaxation time is described by a simple Arrhenius-type law for low temperature, glassy state processes¹ and by the Williams, Landel and Ferry expression² for ' T_g ' processes. We now report results for an elastomer exhibiting a unique relaxation process which remains essentially constant in position and magnitude over a temperature range of more than 100 K.

The block copolymer used was a poly(α -methylstyrene-*b*-dimethylsiloxane) prepared with 'star' geometry $(AB)_4X$, where A represents a poly(α -methylstyrene) block, B a poly(dimethylsiloxane) block and X is a tetrafunctional coupling atom. This polymer was synthesised by Dr D. Jones, Dow Corning Company, by sequential anionic copolymerisation³. The product contained 37.5% (w/w) poly(α -methylstyrene), molecular weight 9,000, with the molecular weight of the B block 15,000. In common with other block copolymers, different morphologies can be achieved by differing the physical treatment⁴. In the present case lamellar morphology could be generated by compression moulding a sheet (523 K, 13 MPa (130 bar)) with considerable flow in the plane of the sheet or by slow casting from benzene on a mercury surface. Dynamic mechanical measurements were carried out either in bending geometry (bars $\approx 20 \times 10 \times 2$ mm) to give Young's modulus (E') or in shear sandwich geometry (cubes with side 2 mm) to give the rigidity over wide ranges of temperature and frequency on a slightly modified version of a phase- and amplitude-measuring mechanical spectrometer previously reported^{5,6}.

Fig. 1 Frequency dependence of mechanical loss factor ($\tan\delta$) and Young's modulus (E') for a benzene-cast sample (294 K) in the bending mode with different clamped lengths as indicated.

Results are shown in Fig. 1 for the benzene-cast sample in a bending mode perpendicular to the sheet direction at 294 K. A clear mechanical loss peak occurs at about 90 Hz and the data remain constant with temperature as shown in Fig. 2. Proper working of the apparatus was checked using standard samples (a high tensile steel bar and a Kraton 101 (Shell) block copolymer) with the results reported in Fig. 1; no abnormalities were evident. Further checks were made by measuring five bars of different lengths of the copolymer under study. The data all lie on the same curve, indicating the reality of the result and the accuracy of the measurements.

Both methods used to produce the lamellar morphology also cause orientation of the lamellae in the plane of the cast or moulded sheet. Small angle X-ray diffraction has been used to characterise both the lamellar spacing and orientation, using both slit and pinhole optics as described previously⁷. Four orders of diffraction are observed, with the ratio of the derived d spacings 1:0.52:0.335:0.254 (from pinhole optics and photographic detection) for the moulded sample and 1:0.489:0.328:0.242 for the benzene-cast sample giving certain evidence of lamellar structure. Pinhole data were used to establish that uniaxial symmetry exists about the normal to the plane of the sheet and to evaluate the orientation function⁸ $\langle \cos^2\phi \rangle$ where ϕ is the angle between lamellar planes and the perpendicular to the sheet. The orientation function is 0 for perfect orientation and 0.333 for random orientation. The benzene-cast sample gave $\langle \cos^2\phi \rangle = 0.215$ and the more highly orientated, moulded sample $\langle \cos^2\phi \rangle = 0.016$.

The mechanical properties of these oriented systems will clearly be anisotropic and their directional dependence has been studied for the experimentally accessible situations, which will be reported by us in full elsewhere. Cubes were cut from the sheet of the benzene-cast sample and clamped so that shearing occurred on the faces of the sheet (geometry 1) and perpendicular to the sheet (geometry 2). The relaxation processes are shown for the pertinent samples in Fig. 3. The simplest case of shearing in the plane of the lamellae (geometry 1) produces a low modulus (10 MN m⁻²) and also a low magnitude transition, whereas

shear perpendicular to their plane (geometry 2) produces a larger loss peak. This indicates that shearing processes alone between lamellae are not responsible for the mechanical loss. In the Young's modulus measurements, the highly oriented, moulded sample exhibits a low relaxation magnitude whereas the corresponding benzene-cast sample with inferior orientation yields a large relaxation magnitude, as does shear with geometry 2. This is good evidence that bending of lamellae is a key feature of the loss process, with lamellae at large angles to the stress direction deforming by bending before undergoing possible rotation and shear.

The results do not conform to the simple interlamellar shear model of Iwayanagi⁹ nor to the more refined model of McCrum and Morris¹⁰, both of which were proposed for semi-crystalline polymers. Two models are now proposed for the relaxation processes: (1) cantilever bending with relaxation by interlamellar shear and rotation, and (2) cantilever bending in a viscous medium. Each is a 'pack of cards' model with sheets of glassy state poly- α -methylstyrene alternating with sheets of lightly cross-linked polydimethylsiloxane. The layers bend under stress with viscous resistance from the accompanying interlamellar shear. The thickness of the poly- α -methylstyrene phase (h) and of the polydimethylsiloxane phase (d) are both small (~ 100 Å) compared with the largest in-plane dimension (l), expected to be ~ 1 μ m. The difference between the models is that in case (1) the lamellae are rigidly constrained at a domain boundary at one end only so that each can bend only as a rigidly clamped cantilever, whereas in case (2) the lamellae are only loosely constrained at one end so that they can rotate and give rise to deformation by interlamellar shear. In model (1) each glassy-state lamella bends as a separate cantilever giving rise to different displacements on the top (extended) and bottom (contracted) surface of each. The glassy lamellae can only bend, therefore, if the viscous silicone phase is simultaneously sheared. Voigt retardation time (case (1)) of this model is

$$\tau_1 = \frac{3\eta l^2}{E'h\pi n}$$

where E' is the in-phase component of the glassy lamellar Young's modulus, η (strictly G''/ω) the viscosity of the silicone rubber phase and n the number of lamellae in the domain. Model (2) allows bending by the above scheme (with retardation time τ_1) but also allows a subsequent relaxation of stress through

Fig. 2 Temperature-independent mechanical loss factor ($\tan\delta$) and Young's modulus (E') for a benzene-cast sample in the bending mode at the frequencies shown.

Fig. 3 Mechanical loss factor ($\tan\delta$) in the frequency plane, at 293 K, for moulded (\square) and benzene-cast (—) samples in the bending mode and benzene-cast samples also in shear, in the plane of the sheet (\circ) and normal to the plane of the sheet (\triangle).

interlamellar shear with loss of the bending deformation. This gives rise to a Maxwell model situation with a relaxation time

$$\tau_2 = \frac{3l^4\eta}{5E'dh^3n^2\tan^2\phi}$$

Details of these derivations will be given by us elsewhere. Differences between relaxation and retardation times are fairly trivial because of the low relaxation strengths involved.

Selection of lamellar parameters from SAXS (small angle X-ray scattering) and volume fractions should now allow tests of the relations for τ_1 and τ_2 . For the benzene-cast sample $h = 82 \text{ \AA}$, $d = 153 \text{ \AA}$ and for the moulded sample $h = 98 \text{ \AA}$, $d = 182 \text{ \AA}$. Evaluation of l and n should be feasible by electron microscopy, but sectioning problems have so far made this intractable. From electron micrographs of similar lamellae-forming block copolymers¹¹⁻¹³ and the sharpness of the SAXS scattering peaks, we expect $l \sim 1-10 \text{ \mu m}$ and $n = 30-300$ per domain. E' for poly- α -methylstyrene has been obtained as $2.5 \times$ shear moduli values of Heijboer¹⁴ and η as $E''/3\omega$ from the data of Langley and Ferry¹⁵. We note that $(G''/\omega) = 2.3 \times 10^3 \text{ N s m}^{-2}$ at $\omega = 1$, but decreases to 7.3 N s m^{-2} at $\omega = 1,000$. We will select an approximate value of 10^3 N s m^{-2} corresponding to the centre of the present frequency range but strictly this parameter should be adjusted with frequency. Using the upper estimates for l and n we obtain frequencies of maximum damping $f_1 = 90 \text{ Hz}$ and $f_2 = 4 \text{ Hz}$. The plateau of loss at low frequencies can thus be understood as arising from a range of relaxation times from model (2) which depends on orientation. Domains with lamellae parallel to the stress direction will have $\langle \tan^2\phi \rangle \rightarrow \infty$ and $\tau_2 \rightarrow 0$ and vice versa. The peak in the data at 80–100 Hz is well predicted by the f_1 value above.

Further evidence in favour of this interpretation has been obtained by swelling the block copolymer in silicone fluid of molecular weight 2,000 and viscosity $5 \times 10^{-3} \text{ N s m}^{-2}$. The only effect of this is to increase the silicone polymer thickness d , to decrease its dynamic viscosity and to change the domain orientations to a more random situation (we will take $\phi = 45^\circ$). SAXS showed that, within experimental error, d increased as predicted from unidirectional swelling (16.3%) of the silicone polymer, giving an observed value of d of 180 \AA (an increase of 17.6%). The viscosity of the final silicone phase (140 N s m^{-2}) was evaluated assuming that each fluid obeys the Doolittle equation $\ln\eta = A - B(1/f)$ with constant coefficients and simple additivity of free volume. The damping maxima (swollen system) are predicted to be at 800 Hz and 8 Hz. The experimental data in Fig. 4 give encouraging agreement, with

two clear regions of loss now apparent at $f_1 > 100 \text{ Hz}$ and $f_2 \sim 1 \text{ Hz}$.

The temperature independence of the loss processes in the bulk samples can now be recognised as a fortuitous constancy

Fig. 4 Mechanical loss factor ($\tan\delta$) and Young's modulus (E') in the frequency plane at 293 K, for a benzene sample swollen with silicone oil. Loss data at 230 K (\bullet) now shows some temperature dependence.

in the ratio $\eta(\text{rubber})/E'(\text{glass})$ with temperature. The swollen sample does not exhibit constancy with temperature, because of a more rapid decrease of η with temperature.

The mechanisms for mechanical loss in the copolymers discussed here are expected to give rise to analogous loss processes in other lamellae-forming block copolymers and in crystalline polymers.

Re-examination of monotony threshold hypothesis in bird song

HARTSHORNE^{1,2} has suggested that a relationship exists between the degree of versatility and continuity in bird song. According to this view, singing which is relatively continuous, with pauses between successive songs relatively short when compared with the length of the song, would tend to be highly monotonous unless successive utterances were variable in pattern.

Hartshorne lent support to his hypothesis by showing a rough correlation of versatility with continuity³. Continuity was calculated by dividing the song length by its cadence (song length + length of following silent interval). A bird with a ratio ranging from 0 to 0.20 was termed a discontinuous singer, 0.20 to 0.50 a semi-continuous singer, and 0.50 to 1.00 a continuous singer. A versatile species was originally defined as one in which "each normal individual... has a repertoire of four or more distinct songs" all or most of which appear "in no particular order" in singing bouts lasting more than 1 or 2 min⁴. A species that is repetitious, "especially if the song is brief and simple, relatively lacking in interval variety of pitch, rhythm, and so on" is non-versatile⁴. Semi-versatile species fall between the two extremes. When a species was categorised simultaneously as discontinuous, semi-continuous, or continuous, and versatile, semi-versatile, or non-versatile in a three by three table, Hartshorne found that most species fell on a diagonal connecting discontinuous-non-versatile and continuous-versatile (Table 1a).

Hartshorne exploited data obtained mainly by ear. Here we present an assessment based principally on information recorded on tape. A literature search resulted in usable data for 39 species of birds, most of which are found in North America. Data for each bird included song length, number of songs in the repertoire and intersong interval, the last being in some cases derived either for the cadence, or from estimates of number of songs per min. Additional data were found for other species—most commonly song length—but species for which all three measures were not available were excluded from consideration.

The definition of song, and therefore song length, may not be consistent from worker to worker, but each worker's own definition of song length was used even though this may introduce some ambiguity in interspecies comparison. Thus for the mockingbird, Wildenthal⁵ noted that "Hartshorne apparently measured the duration of units corresponding to the groups or phrases of the present study, and thus he included silent periods

Table 1 Data compiled by Hartshorne (a) and the data reported here (b) categorised by versatility and continuity

a	Non-continuous	Semi-continuous	Continuous
Versatile	0?	4	9
Semi-versatile	6	24	5
Non-versatile	40	11	1?

b	Non-continuous	Semi-continuous	Continuous
Versatile	10	14	3
Semi-versatile	0	6	0
Non-versatile	2	4	0

between syllables and syllable clusters in the performance time". Wildenthal noted that mockingbirds were only semi-continuous if intersyllable periods were included in the performance time; therefore Table 2 lists a weighted average of mockingbird syllable-pattern length compared with intersyllable pattern length, which gives a percentage performance time within the range Wildenthal reports as comparable to Hartshorne's figures. For other species as well, averaged figures are included when a range of values was given. In the case of five species, repertoire size was listed only as large when the number of patterns or combinations of patterns became too numerous to estimate accurately. The rose-breasted grosbeak for example may change only a few elements in each successive utterance, producing a new combination, or song, each time⁶; it also has unusually long pauses between songs (Fig. 1).

Song length for each species was divided by cadence to produce a percentage performance time. Using Spearman's rank-correlation coefficient our first test compared repertoire size and percentage performance time, which should be significantly correlated if Hartshorne's predictions are valid; however, no significant correlation was found ($r_s = 0.20$, not significant). Even a simple three by three categorisation of these data gave results markedly different from those of Hartshorne (Table 1b). Song length compared with repertoire size also was not significantly correlated ($r_s = -0.15$, not significant).

Clearly these data do not support Hartshorne's hypothesis. Possible differences in the measurement of versatility and continuity between these data and Hartshorne's require comment. By Hartshorne's original criteria, perhaps as many as 27 out of the 39 species examined would qualify as versatile, although

Fig. 1 Correlations of intersong intervals with duration of song (a) and size of repertoire (b). Numbers correspond to species listed in Table 2.

Table 2 Song data for various species of birds

	Species	Repertoire size (songs)	Song length	Intersong interval	Percentage of performance time	Reference

Solitary vireo is listed twice as the Eastern and Western populations have different song data

our list does not disqualify birds showing only "eventual" versatility—birds such as the cardinal which, though having a large repertoire, may sing only one or two songs for a period of time before changing to others. Some variability (for example, song length, number of repeated elements) is found even in the single song type of the chipping sparrow⁷, and Hartshorne, discussing Hutton's vireo as a possible exception to his hypothesis suggests that a slight "change of key" may render the single, repetitive song less monotonous over time. Nevertheless ranking versatility by measuring repertoire size seems a reasonable approach, particularly given the ability of spectrographic analysis to detect differences between song patterns.

The use of average values for song length and intersong interval may also conflict with Hartshorne, who cites instances of unusually continuous singing in versatile birds that normally sing quite discontinuously. There is no reason to suppose, however, that non-versatile discontinuous singers might not show similar examples of more rapid singing. If the monotony threshold hypothesis is to have practical predictive value, it should apply over the broad range of bird songs making up our averaged figures.

In spite of the lack of significance in the two comparisons, two significant correlations in the data were found. Song length and intersong interval gave a strong positive correlation ($r_s = 0.60$, $P < 0.05$), as shown in Fig. 2. This suggests that each species in fact tends to sing in a manner that uses a sound-silence ratio similar to other species, but using a different rhythm, or cadence. These differences in rhythm may be an important quality differentiating one bird's song from another. The same sort of relationship of sound to silence can be found in syllable structure of the cardinal—short syllables being followed by short pauses and longer syllables being followed by longer pauses⁸. Both sorts of data emphasise the fundamental rhythmical quality of song, and it is interesting to speculate that this quality may in part be related to the physiology of vocalisation in birds. The process of respiration perhaps places constraints on song and syllable lengths as well as the intervals between them⁹. Alternatively, these temporal rhythmical relationships may be related to the effectiveness of song in overcoming environmental noise. Repetitive songs, or elements of songs produced at predictable intervals, may provide a high degree of redundancy which would provide for more effective reception by listeners.

Finally, a negative correlation between interval length and repertoire size ($r_s = -0.39$; $P < 0.05$, Fig. 1) may be viewed as supporting Hartshorne's basic notion of temporal differences between versatile and non-versatile species, while suggesting that percentage of performance time is not a good measure of it. Longer intervals between songs in more versatile birds might easily lead a field observer to suppose that continuity, rather than cadence, correlates with versatility. In view of our findings, a relationship between versatility and percentage of performance time is by no means general or predictable.

Highly fertile form of the aggressive strain of *Ceratocystis ulmi*

THE ability to recognise the aggressive and non-aggressive strains of *Ceratocystis ulmi* in culture¹ has enabled us to survey the *C. ulmi* population in the field and thereby monitor any variation that might indicate a change in the course of the present epidemic of Dutch elm disease in Britain. When sampling from diseased elm twigs in the outbreak areas, we have found that while most wild isolates can be assigned to the two strains, there also exist in low frequency (about 2%) isolates with some affinity to the 'fluffy' aggressive strain but which produce small black-brown sclerotium-like bodies throughout the culture and are dark centred because of the presence of brown pigment. We show here that these isolates are a highly fertile form of the aggressive strain, with a special function in the perithecial, or sexual stage of the fungus.

Production of perithecia in *C. ulmi* usually requires the pairing of the two mating or compatibility types, A and B (ref. 2). During routine screening of wild isolates of the aggressive strain for compatibility type, after the method of Holmes³, autoclaved

Fig. 1 Mating reactions of *C. ulmi* isolated on elm twigs. Each diagram (a–g) represents the reaction pattern of an unknown isolate when tested against a standard non-aggressive A type, an aggressive B type, and on its own as a control, with three replicate twigs in each case. Perithecia after 1 month at 18 °C: —, nil; +, rare; ++, occasional; +++, frequent; +++, abundant. Reaction patterns: a, normal A type reaction (as found with non-aggressive isolates); b, normal B type (as found with non-aggressive and aggressive isolates); c, aggressive B type with pseudoselfing at *; d, F₁ fluffy B type, e, F₁ proto A type, with pseudoselfing at *; f, g, wild proto A types, with pseudoselfing at *.

Fig. 2 Perithecium formation by *C. ulmi* on malt agar. *a*, Protoperithecia formed in a culture of a proto isolate (\times about 65). *b*, Mature perithecia formed at the junction of a proto and a fluffy isolate, showing typical long perithecial necks and oozing blobs of ascospores (arrowed; \times about 25). *c*, Formation of a black line of perithecia (arrowed) and a white felty zone line at the junction of a dark pigmented proto (left) and a fluffy (right) isolate. Culture incubated for 12 d in darkness at 18 °C, followed by daylight. *d*, Wild proto isolate S6. Culture incubated in darkness at 18 °C.

peeled elm twigs were dipped first in shake cultures of the unknown isolate, and then after incubation for 1 week at 18 °C, dipped again in a shake culture of a standard A or B tester strain. Control twigs were dipped in the unknown isolate only. No isolate gave a type A reaction (Fig. 1*a*) and most gave a clear-cut type B reaction, forming perithecia with the A tester only (Fig. 1*b*). Some isolates, however, while behaving as type B, occasionally formed scattered perithecia on the control twigs (Fig. 1*c*). As all isolates tested were originally derived from single spores, this 'selfing' phenomenon was particularly curious. Ascospores from such 'selfed' perithecia of three isolates, G11, G29 and S46 were therefore spread on malt agar, and retained on the bench top for observation. After 2 weeks the resulting colonies were seen to be producing abundant fertile perithecia (Fig. 2*b*), an interesting development as perithecia have normally been obtained only on sterilised elm bark or sapwood. The perithecia seemed to be forming at the junction of light and dark coloured colonies as a result of the maturation of numerous small spherical black-brown 'protoperithecia' (about 30–55 μ m, Fig. 2*a*).

To investigate the phenomenon in more detail, fifty single ascospore germings picked off from further spreads of isolate G11 were examined for growth rate and cultural characters on 2% Oxoid Malt Extract Agar at 18 °C. They varied significantly in growth rate, with a range which fell within that normally encountered in aggressive isolates (Fig. 3*a*). On the basis of culture morphology, however, they fell into two groups in a nearly 1:1 ratio. Isolates in one group resembled the parent aggressive isolate in their fluffy morphology¹. Isolates in the other group had some fluffy characteristics but, in contrast, were dark pigmented and also formed considerable numbers of protoperithecia. These isolates were therefore called protoperithecial ('proto'). The mean growth rate of the proto progeny (4.05) was significantly lower ($P < 0.01$) than that of the fluffy progeny (4.25). Ascospore progeny of two other isolates, S46 and G29, also fell into the two groups. With G29 progeny behaviour was similar to that for G11 but in S46 complete separation of the proto and fluffy progeny occurred for growth rate, with the proto isolates growing very much more slowly (Fig. 3*b*). When F_2 ascospores of G11 and S46 were sampled

from perithecia developing in the F_1 ascospore spreads, the process repeated itself, the progeny again separating into proto and fluffy groups.

As Fig. 3 shows, there was considerable variation in growth rate within the two groups. Variation also occurred in morphology, for example, in the pigmentation and abundance of protoperithecia in the proto form, and in the appearance of the aerial mycelium in the fluffy. This variation was particularly marked in the F_1 line of G11 derived by mixing and spreading the ascospores of 20 perithecia from first the F_2 and then the F_3 lines. Several new cultural types occurred within both groups.

The presence of perithecia at the junction of light and dark colonies suggested the involvement of both proto and fluffy progeny types in perithecial formation. A fluffy progeny isolate was therefore paired with its proto sibling on malt agar. Where the two colonies met, a zone of dense white felty mycelium was formed, and later a line of fertile perithecia developed (Fig. 2c). The ascospores again segregated 1:1 for the two types. Whatever their origin, any combination of proto \times fluffy progeny isolates formed perithecia, but fluffy \times fluffy and proto \times proto pairings did not. Furthermore, any wild fluffy isolate behaved in the same way as the fluffy progeny isolates. This suggested either stimulation of selfing, or cross fertilisation between the fluffy and proto types. When a proto progeny culture was seeded with conidia of a fluffy isolate, perithecia sometimes developed at the site of conidial application. This did not happen when a fluffy progeny isolate was seeded with a proto isolate, indicating that in a proto \times fluffy pairing, it is the protoperithecia of the proto culture which mature. Ability of the fluffy to fertilise the proto was demonstrated when ascospores resulting from the seeding of protoperithecia with a fluffy isolate tolerant to the fungicide MBC (ref. 4) segregated for MBC tolerance.

These results suggested a difference in compatibility type between fluffy and proto isolates. In tests of F_1 progeny of G11 and S46 on elm twigs the fluffy isolates gave a normal B-type reaction (Fig. 1d). Proto isolates gave a very strong A-type reaction and also formed numerous perithecia in patches on the control and A tester twigs (Fig. 1e). This showed that the proto is a highly fertile form of the A compatibility type and has, in addition, a marked tendency to 'self'.

It was already evident that proto progeny obtained from 'selfed' aggressive isolates closely resembled in morphology the dark sclerotial types found occasionally in nature (Fig. 2d). This similarity was confirmed when: (1) pairings between dark sclerotial (hereafter called 'wild proto') isolates and fluffy isolates on malt agar resulted in the formation of fertile perithecia; (2) progeny from these perithecia segregated 1:1 for proto and fluffy; (3) wild proto isolates showed a strong A compatibility reaction with a tendency to 'self' on control twigs (Fig. 1f and g); and (4) ascospores from such 'selfed' perithecia segregated 1:1 for proto and fluffy. One such wild proto isolate (T7) with a slow growth rate (about 2.8 mm d⁻¹) produced typical fast-growing fluffy progeny (range of five isolates 3.1–3.8 mm d⁻¹) as well as slower growing proto progeny (range of five isolates 2.7–3.2 mm d⁻¹).

This indicates that the fluffy type can be derived from a proto parent as well as the proto type from a fluffy parent and highlights the need to understand the mechanism by which this occurs. The evidence cannot be reconciled with the non-parental type having arisen by true selfing in a diploid or polysomic line, a situation which would in any case be most unusual in an ascomycete. Indeed the consistent 1:1 segregation of the two types suggests instead a single gene difference in a haploid. In this situation, the non-parental genotype could either arise by mutation or be pre-existing within the parent as a component of a heterokaryon. Because the isolates examined were derived from single uninucleate conidia⁵, and because successively 'singled' proto isolates 'self' on twigs, the origin of the phenomenon in heterokaryosis seems unlikely. On present evidence we prefer the hypothesis that within the fluffy B type mutation to proto A type occurs at a single locus. Proto nuclei arising within the mycelium of the vegetatively growing fluffy isolate on malt

Fig. 3 Growth rate distribution of F_1 progeny derived from 'selfed' perithecia of aggressive isolates of *C. ulmi*. a, Progeny of isolate G11, b, Progeny of isolate S46. Proto progeny stippled, fluffy progeny white. Arrows show parental growth rates, and bars indicate least significant difference between isolates at $P < 0.05$.

agar are normally suppressed. When, however, an elm twig is dipped in a shake culture (in which a yeast-like budding phase occurs) spores containing proto nuclei are able to develop, resulting in localised A \times B fertilisation and maturation of perithecia. Resulting ascospores segregate 1:1 mutant (proto): wild type (fluffy). With this 'pseudoselfing', background variation such as growth rate among both proto and fluffy progeny could be due to segregation of mutations at other loci, and perhaps to some cytoplasmic variation. A similar explanation based on the reverse mutation could apply to the origin of the fluffy from the proto type.

Preliminary data suggest that the postulated proto locus has some influence on pathogenicity as well as on growth rate and culture morphology. An inoculation experiment on 5-yr-old clonal English elm, *Ulmus procera*, using techniques described earlier¹ with four replicates, showed that while three wild proto isolates caused very much more defoliation than two non-aggressive isolates, they caused significantly less ($P < 0.05$) than twelve wild fluffy aggressive isolates; mean percentage defoliation at 8 weeks being 2.3% for the non-aggressive, 50.8% for the proto and 75.9% for the fluffy isolates.

The occurrence of the protoperithecial form of the aggressive strain, and the phenomenon of pseudoselfing, reveal previously unknown properties in *C. ulmi* with considerable ecological implications. Perithecia occur naturally in beetle breeding galleries within the bark of diseased elms and the ascospores, together with asexual spores, are thought to be carried by the newly emerging beetles in the spring. Until now it has been assumed that for perithecial formation the absence of an aggressive A type in Britain would mean that the aggressive strain would have to hybridise with the non-aggressive strain, leading to a decline in pathogenicity⁶. It is now clear that this is not the case and that an aggressive B type could undergo pseudoselfing to produce two progeny genotypes, one the fluffy B form, close to the parent itself, and the other the highly fertile proto A form. Furthermore, in elm bark the latter would presumably produce abundant protoperithecia, which would be available for fertilisation, whether by pseudoselfing or by outcrossing with available B types. It seems that the aggressive strain could thus maintain itself even where perithecial formation rather than asexual reproduction was at a premium. The natural balance between the two forms would presumably depend on the relative selection pressures towards such attributes as perithecial formation, saprophytic ability within bark and pathogenicity.

The role of the proto form in the present epidemic is being investigated. The low frequency of proto isolates in twig samples suggests that in the pathogenic phase of the fungus this form is presently less fit than the fluffy form. Some perithecia from bark in the main outbreak areas have, however, produced equal numbers of fluffy and proto progeny. Furthermore, a reinvesti-

gation of the ascospore progeny from the perithecia found in beetle galleries of the imported rock elm logs examined in January 1973 (ref. 7) has shown that these too consist of proto and fluffy forms. Thus these perithecia must have resulted from proto \times fluffy outcrossing or pseudoselfing.

Our laboratory experiments have shown that pseudoselfing and proto \times fluffy outcrossing can result in significant variation among progeny. In nature this could lead to the appearance of new genotypes, and in a situation in which selection for aggressiveness were relaxed, might well contribute to a decline in the pathogenicity of the present *C. ulmi* population and thus of the epidemic.

We thank Polly Smith and Andrew Syred for technical assistance and Drs Mark Anderson and Chris Caten for comments on the manuscript.

Morphine withdrawal response and central cholinergic activity

MOST of the different neurotransmitter systems have been implicated in opiate withdrawal. Frederickson and Pinsky¹ suggested a primary role for acetylcholine (ACh) in both the development and the expression of dependence on morphine but the specific role of cholinergic mechanisms in opiate withdrawal is not yet clear and deserves further attention. The hypothesis of the role of ACh in the expression of withdrawal phenomena, on which most earlier experiments were based, was that of the 'cholinergic excess', first postulated by Paton². Tests of this hypothesis in various laboratories have, however, produced conflicting results and thus confusion rather than clarification of the role of cholinergic mechanisms in the withdrawal syndrome³⁻⁹. Unfortunately, many such studies have neglected to differentiate between peripheral interference with expression and central interference with initiation of the signs of withdrawal by the various drugs studied. Our experiments were designed to eliminate this particular factor, which has contributed to much of the conflict. The results clearly illustrate the confounding effect of failure to separate peripheral from central cholinergic effects and suggest that the exact opposite of the cholinergic excess theory is the actual nature of the central cholinergic role in the morphine withdrawal syndrome.

Male albino rats (Sprague-Dawley, Harlan, 140-160 g) were made morphine-dependent by the administration of a slowly absorbed suspension of morphine base in mannide monooleate (300 mg kg⁻¹, subcutaneously) as described previously^{8,10}. Withdrawal was precipitated 48 h later, which is the approximate time of peak withdrawal response¹⁰, by the injection of naloxone (0.03-3.0 mg kg⁻¹, subcutaneously) and withdrawal severity was assessed by a point-scoring technique modified slightly from that described previously¹⁰ by weighting the signs. The range of scores possible for each sign is given in the legend to Fig. 1. In the present experiments the withdrawal signs scored were grouped before analysis as follows. Group 1: those

Fig. 1 *a*, The effects of eserine sulphate (0.25 mg kg⁻¹, intraperitoneally, (□) and atropine sulphate (5 mg kg⁻¹, intraperitoneally, (●)) on the severity of the naloxone-induced withdrawal response of morphine-dependent rats. The points refer to the means (± s.e.) of the total withdrawal score per animal ($n = 6$ rats per point). The signs scored, with the range of possible scores for each sign, follow; group 1 signs: wet dog shakes (0-12), escape jumping (0-36), escape digging (0-12), yawning (0-12), ptosis (0-8), penile erection (0-12), irritability to handling (0-6), reaction to poking with sharp object (0-12), restless activity (0-8); group 2 signs: rhinorrhea (0-8), lacrimation (0-12), salivation (0-18), diarrhoea (0-8), seminal emission (0-8). Control animals received saline before naloxone. *b*, Effects of eserine sulphate (0.25 mg kg⁻¹, open bars) and atropine sulphate (5 mg kg⁻¹, hatched bars) on group 1 as compared with group 2 signs. The data are presented as percentages (mean ± s.e.) of 100%. The scores for the group 1 signs and the scores for the group 2 signs were determined separately. The data presented in this figure were obtained from a total of 54 rats, 18 per treatment mode. A, Atropine sulphate; E, eserine sulphate.

signs with a strong voluntary component which were found to be influenced by muscarinic or antimuscarinic drugs by action in the central nervous system; and group 2: those signs with a strong autonomic or peripheral parasympathetic component whose peripheral expression was found to be influenced by muscarinic or antimuscarinic drugs by action in the periphery. The actual signs used for each analysis are given in the legend to each figure. Eserine sulphate and atropine sulphate were injected intraperitoneally 30 min before the challenge with naloxone. When combined treatment was used, either atropine sulphate or atropine methylnitrate was injected intraperitoneally immediately before eserine sulphate.

The total withdrawal score precipitated by various doses of naloxone (0.03-3.0 mg kg⁻¹, subcutaneously) was slightly diminished by treatment with eserine at 0.25 mg kg⁻¹ and similarly with atropine at 5 mg kg⁻¹ (Fig. 1*a*). The apparent paradox of a cholinergic agent, eserine, and an anticholinergic agent, atropine, producing similar effects can be explained if the different possible sites of action are considered. Thus, when the withdrawal signs were separated as described above, it was

apparent atropine did not reduce the severity of the group 1 signs but markedly reduced the score for group 2 signs, many of which are parasympathetic in nature (Fig. 1b). Thus atropine seems to reduce withdrawal severity merely by blocking the peripheral expression of the subset of signs with a strong peripheral parasympathetic component. Conversely, eserine, at the dose used, had no effect on the peripheral signs but did reduce the severity of central signs (Fig. 1b). These results predict that the combination of a central cholinergic agent with peripheral cholinergic blockade should reduce the withdrawal response very effectively. Thus, in the presence of methylatropine, eserine should effectively alleviate overall withdrawal severity. Methylatropine blocks muscarinic receptors in the periphery but does not readily penetrate the blood-brain barrier. We did, in fact, observe a marked dose-dependent reduction in withdrawal severity of morphine-dependent rats after combined treatment with eserine and methylatropine (Fig. 2a). Eserine alone did not have such an effect. The importance of the central cholinergic activity of eserine in reducing the withdrawal response became evident when the effects of combined treatment with eserine and atropine sulphate were examined. Atropine sulphate should have the same actions peripherally as methylatropine, yet, the combination of eserine and atropine did not have the same ameliorating effect on withdrawal as did the combination with methylatropine (Fig. 2a). This is interpreted as attributable to antagonism of the central cholinergic actions of eserine by atropine. An examination of group 1 and group 2 signs separately further confirmed this interpretation (Fig. 2b, c).

Fig. 2 The effects of eserine sulphate (0.3 and 1.0 mg kg⁻¹ subcutaneously) alone ● and in combination with atropine methyl-nitrate ○ or atropine sulphate □ on (a), total withdrawal score, (b), group 1 withdrawal score; and (c), group 2 withdrawal score. The stippled regions on each graph represent the control withdrawal score (mean ± s.e.). The signs used for the total, group 1 and group 2 scores were identical to those listed in the legend to Fig. 1. The data presented in this figure were obtained using 42 rats, 6 rats per point. Naloxone was injected at 0.3 mg kg⁻¹ subcutaneously to precipitate withdrawal. The dose of atropine methyl-nitrate and atropine sulphate used in these experiments was 5 mg kg⁻¹ intraperitoneally.

The higher dose of eserine increased the severity of the group 2 signs and both atropine and methylatropine blocked this effect (Fig. 2c). Thus eserine seems to increase the severity of group 2 signs by a muscarinic action in the periphery. Both doses of eserine reduced the severity of the group 1 signs (Fig. 2b). Atropine blocked this effect; methylatropine did not, but in fact increased the beneficial effect of the higher dose of eserine. These interactions clearly illustrate that eserine must alleviate the severity of group 1 signs by a muscarinic action in the central nervous system.

These results provide further evidence for an important role for acetylcholine in morphine withdrawal but do not support the hypothesis^{2,11,12} of a cholinergic crisis resulting from excessive release of ACh on to supersensitive receptors. On the contrary, the specific derangement in central cholinergic function which occurs after the administration of naloxone to a morphine-dependent animal seems to be a cholinergic deficit. Thus when the interference from cholinergic actions in the periphery is eliminated by methylatropine, eserine relieves the withdrawal response, presumably because of an increase in central muscarinic activity, as it is blocked by atropine.

Frederickson and Pinsky¹ reported that the syndrome which occurs on abstinence morphine withdrawal is biphasic in nature. The early phase seems to coincide with a cholinergic deficit since it is potentiated by anticholinergic treatment, while the later phase seems to have a cholinergic component, since its severity is reduced by treatment with anticholinergic drugs. Labrecque and Domino¹³ have reported a biphasic effect of naloxone also on cortical ACh release in morphine-dependent cats. ACh output was decreased at 15 min after 1.0 mg kg⁻¹ of naloxone while an increase was found at 45–105 min. Thus the naloxone-precipitated withdrawal response seems to be an accelerated and accentuated correlate of the spontaneous withdrawal syndrome. The studies of ACh release should be repeated on rats, but it is interesting that the withdrawal response precipitated by naloxone, reported here as being a result of a central cholinergic deficit, occurred dramatically within the first 15 min of naloxone injection, corresponding to the time the decrease in output of cortical ACh was observed by Labrecque and Domino¹³.

In conclusion, the present results provide an explanation for the previous conflicting reports³⁻⁹ of the effects of cholinergic and anticholinergic drugs on opiate withdrawal, since either an increase or a decrease in withdrawal severity could be expected, with either a cholinergic or an anticholinergic agent, depending on the sign or signs examined. The early phase of the opiate withdrawal response seems to correspond to a central cholinergic deficit and I suggest the most effective alleviation of withdrawal stress requires the unique combination of a central muscarinic action plus a peripheral muscarinic blockade.

I thank Mr Vigo Burgis for technical assistance.

Low levels of photoreactivating enzyme in xeroderma pigmentosum variants

XERODERMA pigmentosum (XP) is a recessive, hereditary disease in which patients develop malignancies on areas of

Table 1 PRE and pyruvate kinase levels in normal and XP variant cells

Cell line	Pyruvate kinase* activity (% normal)	PRE activity† (% normal)
Normal		
HESM	100	100
Variants		
XP4BE	81.4	11
XP13BE	40.6	9
XP7TA	104	4
XP30RO	80.2	56

*Determined by the method of Ibsen and Trippet¹¹.†Cells were grown collected and assayed as described previously^{5,9}. Protein concentrations were determined by the method of Lowry¹². Typical levels of enzyme activity for normal cells were 600–620 pmol mg⁻¹ min⁻¹. All values were the average of at least three independent determinations except for XP30RO, which had two.

skin exposed to sunlight¹. Although fibroblasts from most XP individuals are deficient in excision repair of damage to DNA (classical XP), those from a few individuals (XP variants) having the usual clinical signs of XP seem to have normal excision capacity². Photoreactivation is a DNA repair process in which the photoreactivating enzyme (PRE) monomerises pyrimidine dimers induced by ultraviolet light³. As PRE is present in normal human cells⁴, but only at reduced levels in classical XP cells⁵, we thought that the XP variants may also be defective in PRE activity. We therefore measured this activity in fibroblasts from four XP variants (Table 1) and found that Variants XP30RO, XP4BE, XP13BE, and XP7TA have 56, 11, 9, and 4% of the normal level of PRE activity, respectively.

Are the lower levels of PRE an intrinsic property of the cells or an artefact of culture or assay conditions? The high levels of PRE activity in the normal cells have been shown to be neither an artefact of mycoplasma infection of the normal lines nor of age of the cell donor at biopsy⁵. We have also examined the possibility that the low PRE activity in XP variants may result from: systematic loss of enzyme activity with culture age; unfavourable enzyme assay conditions; presence of inhibitors of PRE activity; or slower growth rates of the XP cells leading to general enzyme depression. We found, however, no systematic decrease in PRE activity throughout 10 cell passages; neither an increase nor decrease in pH or ionic strength, nor the omission of Mg²⁺ from the assay mixture, increased the apparent enzyme activity in extracts of XP7TA; mixing experiments indicated that the cell extracts of XP7TA had no effect on the activity of the normal human enzyme; and pyruvate kinase (chosen as the representative enzyme of cellular metabolism other than DNA repair) levels were 40.6, 81.4, 104 and 80.2% of the normal level, for XP13BE, XP4BE, XP7TA and XP30RO, respectively. We conclude that these factors do not play a major part in determining the level of PRE activity measured in our assay. These data imply that the observed low levels of activity were not

artefacts of culture or assay conditions, and may contribute to the depression of total DNA repair capacity in XP variants.

What other processes must be considered in determining the total cellular repair capacity? In addition to photoreactivation, cells have two other pathways for repair of ultraviolet-induced damage to DNA: excision repair⁶ and postreplication repair⁷. Excision repair and photoreactivation act principally as prereplication error-correcting pathways, whereas postreplication repair works to seal gaps presumably generated opposite damaged bases during DNA replication. One measure of cellular excision repair ability is unscheduled DNA synthesis, the ultraviolet-induced incorporation of ³H-thymidine into nuclei of non-S-phase cells. XP4BE, XP13BE, XP7TA and XP30RO can carry out excision repair at almost normal levels (Table 2). Although quantitation of postreplication repair is difficult, Lehman *et al.*⁸ have shown that 1 h after ultraviolet irradiation, the DNA of XP variants is much smaller (and thus contains more unrepaired gaps) than that from normal cells. The data of Lehman *et al.*⁸ for the relative sizes of the DNAs at 1 h postirradiation are shown in Table 2. PRE activity (Table 2) was measured as described previously^{5,9}.

We obtain a rough estimate of the total repair capacity of a cell by adding the values for each of the three processes. The two clinically normal individuals thus have total repair capacities of 300 (for HESM) and 240 (for CeAr). The latter individual is the mother of one normal and five XP children; although she (like other presumed heterozygotes for excision repair¹) has normal unscheduled synthesis, her PRE level is about half normal. This finding indicates that a small loss of repair capacity may be tolerated without apparent detriment.

XP30RO has only mild to moderate clinical symptoms of XP and an intermediate repair capacity of 173, whereas variants with severe symptoms (XP4BE, XP13BE and XP7TA) have even lower repair capacities—143, 141 and 137, respectively.

It is likely that the three repair processes are not equally important in cellular DNA repair *in vivo*. Assignment of a 10-fold greater importance, however, to excision repair than to postreplication repair and photoreactivation led to predictions of similar repair capacities for normal and XP variants, in contradiction to their clinical symptoms. Similarly, assignment of 10-fold greater importance to photoreactivation or postreplication repair led to the prediction that CeAr should be XP instead of normal, or that all XP variants should show the same degree of affliction with XP respectively. It is thus possible that all three repair processes are necessary for normal repair—perhaps because of the lack of overlap of the repair processes or availability of the DNA to the repair enzymes in space or time¹⁰.

In spite of the apparent correlation of the clinical symptoms with the calculated total repair capacity, at least three variables—differential sun exposures of individuals to sun, variable shielding by pigments in the damage and differing ages on clinical examination—make the use of such a simple scheme of computation of DNA repair capacity difficult. The apparent

Table 2 Repair capacities in normal and XP cells

Cell line	Phenotype	Unscheduled* DNA synthesis (% normal)	Relative† DNA size after irradiation (% normal)	PRE Activity (% normal)	Total repair capacity
Normal					
HESM	Normal	100§	100§	100	300
CeAr‡	Normal (ref. 1)	100 (ref. 1)	100§	34	234
Variants

§Although these cell lines were not tested, the values shown are typical for normal (HESM and CeAr) and XP variant (XP13BE) cells, respectively.

correlation of DNA repair capacity with clinical signs or propensity to sunlight-induced skin malignancy—and the severity of such disease—makes it tempting to speculate that there is a direct relationship between the total DNA repair capacity and development of sunlight-induced skin cancer.

This research was supported by the NIH, American Cancer Society and a Research Career Development Award to B.M.S. We thank Dr R. Day, National Cancer Institute for two cell lines.

Rat liver microsomes catalyze covalent binding of ¹⁴C-vinyl chloride to macromolecules

THE occurrence of angiosarcoma and injury of the liver in workers occupationally exposed to vinyl chloride (VC) has focused interest on the fate of VC in the organism. Jaeger *et al.*¹ presented evidence that pretreatment of rats with phenobarbital, which induces the microsomal mixed function oxidase system of the liver, also enhances liver toxicity of VC. They suggested that VC may be transformed by this enzymic system to a reactive epoxide intermediate which has also been considered by some other authors^{2,3}. This intermediate, according to its electrophilic properties, might interact with components of the liver cell. We present here some results which further support this theory.

We incubated 1,2-¹⁴C-VC with rat liver microsomes and an NADPH-regenerating system (isocitrate and isocitric dehydrogenase). Preparation of microsomes and the incubation mixture followed standard procedures⁶. The incubation vessels were connected to an all-glass system containing the radioactive VC substrate which was diluted with atmospheric air, so that incubations could be carried out at different rates of supply of the gaseous substrate. After incubation (90 min) the total uptake of substrate during incubation was determined by measuring the total radioactivity present in the incubation mixture. Irreversible binding of VC metabolites to the microsomal protein was determined after exhaustive solvent extrac-

tions as described previously using other lipophilic substrates^{4–8}. It is known that rat liver converts VC to metabolites such as chloroethanol, chloroacetaldehyde and chloroacetic acid^{3,7}. Therefore extraction of the proteins had to remove the lipophilic VC and the water-soluble metabolites. Exhaustive extraction of the microsomal proteins was achieved using a schedule originally developed for removing metabolites of imipramine⁸. This included precipitation of proteins with ethanol and washing of the precipitate with 70% ethanol, Tris buffer, pH 7.5 (twice), 70% ethanol, absolute ethanol (twice), acetone-chloroform (4:1, twice), and finally 70% ethanol. Irreversible binding of VC metabolites to soluble proteins and nucleic acids which had been added to the microsomal incubation was estimated after adsorption of the lipophilic VC to charcoal (norit A) and subsequent dialysis of the water-soluble metabolites. After these procedures no further radioactivity could be removed from the soluble proteins or nucleic acids if these were subjected to solvent extraction (70% ethanol at –20 °C). The radioactivity which was attached to the protein remained constant during this extraction procedure.

Table 1 shows that supply of NADPH was essential to achieve covalent binding of VC metabolites to rat liver microsomes. In addition, VC metabolites were also bound to albumin when this was added to the microsomal incubation. Non-mercapto-albumin was prepared according to Carlsson and Svenson⁹. This preparation was much less efficient in trapping the reactive intermediate formed from VC by the microsomal enzymes. Concanavalin A (con A), containing no cysteine at all, does not covalently bind VC metabolites, indicating that cysteine participates in the binding reaction. The results are in agreement with the assumption of VC-epoxide being the reactive VC metabolite. Similar conclusions have been drawn for metabolic activation of vinylidene chloride⁹.

Further experiments fitted this concept. Covalent binding of VC metabolites to proteins in our system was depressed by 30% on addition of 1 mM glutathione. Addition of cytosol, which contains glutathione, had a similar effect.

The inhibitor of microsomal cytochrome P450-dependent mixed function oxidations, 1-naphthyl-4(5)-imidazole¹⁰ at a concentration of 10^{–4} M, inhibited covalent binding by 85%.

The finding that VC metabolites can also be bound to RNA (Table 1) seems to be of particular importance with regard to the mechanism of chemical carcinogenesis induced by VC. It is commonly accepted that pre-carcinogens are primarily metabolised to electrophilic ultimate carcinogens which can bind covalently to cellular macromolecules¹¹.

Additional support for the involvement of epoxide in the covalent binding reaction could be obtained from experiments using the xanthine oxidase model system which generates H₂O₂ and the O₂[–] radical¹². These incubations (1 ml) contained: 10 mg albumin, 0.8 mM hypoxanthine, 8 mU xanthine oxidase (Boehringer, Mannheim) and 0.08 mM EDTA, and were exposed to the ¹⁴C-VC-containing atmosphere for 60 min. Control incubations with albumin and 5 mM H₂O₂ showed no covalent binding of ¹⁴C-VC to the albumin, whereas the complete xanthine oxidase system, when taking up 10 nmol ¹⁴C-VC,

bound 12.6 ± 1.2 pmol (mean \pm s.d.; $n = 3$) VC metabolites to the 10 mg albumin. This strongly suggests that O_2^- radicals, which are known to be involved in epoxidation by the microsomal enzyme system¹³, convert VC to a metabolite which then binds covalently to a protein-like albumin.

In accordance with our results Bartsch *et al.*^{9,14} reported that in bacterial test systems VC and also the closely related compound vinylidene chloride are only found to be mutagenic if rat liver microsomes are present to form the ultimately mutagenic metabolite. Pretreatment of the rats with phenobarbital enhances the mutation rate. This also corresponds to the work of Jaeger *et al.*¹ on liver toxicity of VC in phenobarbital-pretreated rats. Thus, the concept of a reactive metabolite of VC involved in carcinogenesis and liver toxicity gains further support.

A genetic basis for resistance to enteric disease caused by *E. coli*

THE K88 antigen on the surface strains of *E. coli* which cause neonatal diarrhoea in piglets^{1,2} is an essential virulence determinant^{3,4} because its adhesive properties enable K88-positive strains to attach to piglet intestinal mucosa^{4–7} and establish in the small intestine⁴. These bacteria multiply to reach abnormally large numbers in the gut⁸ and synthesise enterotoxins that cause diarrhoea and death of infected piglets^{9,10}. K88-positive bacteria, however, do not attach to intestinal tissue from all piglets, and at least two pig phenotypes occur^{6,7}, which we have designated 'adhesive' (signifying that K88-positive bacteria attach to their brush borders) or 'non-adhesive' (K88-positive bacteria do not attach to their brush borders). Phenotypes are the products of two alleles at a single locus which are inherited in a simple Mendelian manner⁷, and the phenotypes of progeny from selected matings support the conclusion that the product of the 'adhesive' allele is dominant over the product of the 'non-adhesive' allele (R. A. G., R. S. and J. M. R., unpublished).

Thus, it seems reasonable to postulate that K88-positive bacteria colonise the gut of 'adhesive' pigs more readily than the gut of 'non-adhesive' pigs, and that 'adhesive' animals are more likely to be susceptible to neonatal diarrhoea caused by these strains. To investigate this possibility, five litters comprising 47 piglets were removed from their dams 2 d after birth

and fed on cow's milk¹¹. Two days later, 1 ml of a suspension containing 10^{10} viable organisms of a virulent K88-positive strain W1 (0149: K91 (B), K88ac(L); H10) of *E. coli* was given to each piglet by stomach tube. Clinical observations were made daily and severely diseased piglets either died or were killed *in extremis* within 4 d of challenge; healthy surviving piglets were killed 5–7 d after challenge. All piglets were necropsied and viable bacterial counts were made on the contents of the intestine. Brush borders were prepared from the small intestine of each piglet and its phenotype was determined⁶.

Twenty-three piglets from the five litters were phenotyped as 'adhesive' and 21 of these piglets died or were killed with clinical signs of neonatal diarrhoea. At necropsy, strain W1 was present in large numbers throughout the gut and was generally dominant in the anterior small intestine. The two 'adhesive' piglets which survived showed no clinical signs of disease and did not excrete strain W1 after challenge.

Twenty-four piglets from the five litters were phenotyped as 'non-adhesive' and 23 survived challenge. These piglets showed no clinical signs of neonatal diarrhoea and did not excrete strain W1. One 'non-adhesive' piglet died 72 h after challenge with mild signs of neonatal diarrhoea but excreted only small numbers of strain W1.

The mean \log_{10} viable counts of *E. coli* in the anterior small intestine of the 23 healthy 'non-adhesive' survivors was 5.8; strain W1 (\log_{10} 5.3) was present in only one of these animals. In contrast, the mean count of strain W1 was \log_{10} 8.2 in 15 diseased 'adhesive' piglets that were killed, and \log_{10} 9.7 in six diseased 'adhesive' pigs that died. In the two healthy 'adhesive' pigs which survived, strain W1 was not detected in the intestine, and in the diseased 'non-adhesive' piglet which died, strain W1 was present in the anterior small intestine (\log_{10} 7.6) but was outnumbered almost 100-fold by other *E. coli*.

These results indicate that the 'adhesive/non-adhesive' phenotype determines whether the K88-positive enteropathogenic strain establishes in the gut and proliferates to cause clinical disease. In the 'adhesive' animals, strain W1 attaches and multiplies to reach large numbers in the small intestine, whereas in the 'non-adhesive' animals, strain W1 is unable to attach and rapidly disappears from the gut. The survival of two 'adhesive' piglets in which strain W1 failed to establish demonstrates, however, that additional factors may prevent attachment and proliferation of K88-positive bacteria in the gut. The death of one 'non-adhesive' piglet with strain W1 in the small intestine indicates that attachment by K88 is not always essential for the pathogenic strain to establish in the gut.

The complex nature of the *in vivo* situation has been emphasised in an experiment in which the expected susceptibility of sucking 'adhesive' piglets experimentally infected at birth was not expressed; these piglets received colostrum from the dam that contained K88 antibodies which are known to be associated with passive protection of piglets against challenge with strain W1^{12–14}. It seems reasonable to suggest that these 'adhesive' piglets were susceptible to infection but passive protection conferred by the K88 antibodies in colostrum and milk prevented the enteropathogenic strain from attaching and multiplying to reach high numbers in the gut.

These results have a number of interesting implications. It seems that the 'non-adhesive' phenotype primarily determines whether an animal will be resistant to infection with K88-positive strains of *E. coli*; however, if 'adhesive' animals receive protective antibodies in mammary secretions, then they may seem to be 'resistant' to infection. Although the nature of the product of the 'adhesive' allele is unknown, study of the K88 antigen has provided, as far as we are aware, the first example of a genetic basis for resistance to enteric disease. As a result, it may be possible to select breeding pigs that have the 'non-adhesive' gene and thus produce progeny resistant to neonatal diarrhoea caused by K88-positive *E. coli*.

In addition to this practical application, it is becoming clear that adhesion to tissue surfaces may be an important mechanism of pathogenicity in several diseases including human bacterial

infections caused by *Vibrio cholerae*¹⁵, and streptococci¹⁶. If the principles that we have demonstrated for K88-positive *E. coli* infection^{4,6,7,12-14} apply more generally, then the outcome of such infections may be determined by the virulence determinants of the microorganism, the phenotype of the host and the immune response of the host or its dam. An understanding of the genetic susceptibility of the host may, therefore, be an essential prerequisite for the interpretation and evaluation of infection experiments with those pathogens which become attached to cell surfaces.

Cadmium resistance and content of cadmium-binding protein in cultured human cells

INDUCTION of hepatic metallothionein (a cadmium-binding protein) is considered to be a protective mechanism in mammals against the toxic cadmium ion. Pretreatment of rats with low doses of cadmium induces the synthesis of metallothionein and also protects against subsequent exposure to an otherwise lethal dose¹. But the role of metallothionein in cadmium resistance is not clear². Restriction of food intake in the rat increases the level of metallothionein³, but does not alter the LD₅₀ of cadmium². Also the synthesis of metallothionein seems to continue for a longer time than the protection against cadmium in both rats and mice^{1,2}. Lucis, Shaikh and Embil⁴ found uptake of Cd in cultured human embryonic fibroblasts, HeLa cells and monkey kidney epithelial cells after 8 d of incubation with Cd. At that time the cells also contained a Cd-binding protein. The authors did not, however, describe growth of the cells in the presence of Cd or development of cell strains resistant to Cd. Webb and Daniel⁵ recently described the synthesis of a Cd-binding protein in cultures of cells derived from the cortex of the adult pig kidney.

We describe here the development of Cd resistance and the relationship between cadmium resistance and cadmium-binding protein (CdBP) levels in cultured human skin epithelial cells.

Human skin epithelial cells (HE cells) NCTC strain 2544 were obtained from American Type Culture collection, Rockville, Maryland and grown in Falcon plastic tissue culture flasks (75 cm²) in Dulbecco's modified Eagle's medium supplemented with foetal calf serum and horse serum as described in ref. 6. Medium was changed every 3 d. Cadmium (20 µM) added to the medium had toxic effects; after 2-3 d the cells altered shape, about 90% of them died and the growth of those remaining ceased. After a lag period of about a week, the cells retained their growth. The Cd concentration was kept at 20 µM and after 5-6 weeks the cells had regained a normal appearance and an almost normal growth rate, that is, a generation time of about 24 h. At that time the Cd concentration was increased

Fig. 1 Growth of human epithelial cells not made resistant to cadmium (a) and human epithelial cells made resistant to 100 µM Cd in the growth medium (b). Both cell lines were grown in medium without Cd added (▲) and with 100 µM Cd added (●).

to 40 µM. The cells again altered morphology, most of them died and the growth ceased temporarily, but in the course of some weeks, the cells regained normal growth. By increasing the Cd concentration in the medium about every 6 weeks, the cells were made resistant to 100 µM Cd in about 30 weeks. After 30 weeks the resistant cells had about the same growth rate in the presence of 100 µM Cd as in Cd-free medium (Fig. 1). This concentration of Cd would kill HE cells not previously exposed to Cd. The resistant cells could be frozen in liquid nitrogen for several months without losing the resistance towards Cd. The cells could also be grown for at least 4 weeks without Cd in the medium without losing Cd resistance. These Cd-resistant HE cells have a generation time of approximately 24 h (like the parent cell line) and the resistance is thus persistent for at least 20 generations without any Cd added to the growth medium.

Growth medium and cells were tested for low molecular weight CdBP by addition of ¹⁰⁹Cd, a gamma emitter, to the cell cultures. To get a maximum uptake of labelled Cd, cultures of resistant cells were grown for at least 3 d in a Cd-free medium before the addition of ¹⁰⁹Cd. Labelled Cd (final concentration 1.3 µM) was then added to the growth medium. After growth

for 24 h in medium containing ^{109}Cd , the medium was collected, the cells were washed twice with 5 ml prewarmed (37°C) medium without Cd, lysed in 10 ml distilled water, and frozen and thawed twice. The cell lysate was centrifuged at 2,000g for 10 min and the supernatant chromatographed on a Sephadex G-75 column (K 16/100) 1.6×79 cm in Tris-HCl buffer 0.001 M, pH 8.6.

The column was calibrated with bovine albumin, trypsin inhibitor soyabean protein and cytochrome *c*. The result of gel filtration of the lysate of HE cells resistant to $100\ \mu\text{M}$ Cd grown in the presence of ^{109}Cd is shown in Fig. 2. The elution volume for peak 2 was the same as for cytochrome *c* and corresponds to a molecular weight of about 12,000.

Fig. 2 Gel filtration (Sephadex G-75) of lysate of: *a*, human skin epithelial cells made resistant to $100\ \mu\text{M}$ Cd; *b*, cells not resistant to Cd; *c*, growth medium (Dulbecco's modification of Eagles' medium supplemented with 17.5% serum and with $1.3\ \mu\text{M}$ ^{109}Cd). Tube 40 represents the exclusion volume (molecular weight about 70,000), tube 80 corresponds to a molecular weight of about 12,000; tube 120 is the total volume of the column and corresponds to a molecular weight of less than 1,000–3,000.

Figure 2 also shows the result of gel filtration of lysate of HE cells not resistant to Cd also grown for 24 h in the presence of $1.3\ \mu\text{M}$ ^{109}Cd . No peaks corresponding to CdBP of molecular weight about 12,000 could be detected. Growth medium likewise did not contain any CdBP with a molecular weight of 12,000. A Cd peak was demonstrated corresponding to a protein eluted with the void volume, which means that its molecular weight is above 70,000. Both types of cell had a Cd peak corresponding to the total volume of the column, that is Cd conjugated to some compound with a molecular weight of less than 1,000–3,000. HE cells resistant to $100\ \mu\text{M}$ Cd, but grown without any Cd added to the medium for 4 weeks, also contain a Cd-binding macromolecule with a molecular weight of 12,000. After about 20 generations in Cd-free medium these cells were still resistant to $100\ \mu\text{M}$ Cd and they also still had CdBP with a molecular weight of 12,000. We do not know,

however, whether minute amounts of Cd were still present in the cells at that time. In some experiments Cd isotope was added to the medium and the cell lysate after collection of the cells. The results were essentially the same; CdBP of molecular weight about 12,000 could be demonstrated in lysates from Cd-resistant cells, but not in the growth medium or in HE cells not exposed to Cd.

In these experiments we have thus found a good correlation between Cd resistance and the appearance of CdBP. Since our epithelial cells have been derived from human skin, these experiments show that CdBP may be produced in organs other than liver and kidney. Two different cadmium-binding proteins (metallothioneins) have been purified from human livers by Bühler and Kägi⁶. They determined the molecular weights to be about 6,100 for the peptide moiety. Nordberg *et al.*⁸ isolated and described metallothionein from rabbit with a molecular weight of about 6,000. Weser *et al.*⁹ found, however, a molecular weight of about 12,000 for rat and chicken. They discuss whether their protein might be a dimer of the rabbit protein isolated by Nordberg *et al.*⁸. The protein which seems to develop parallel to the resistance to cadmium in the cells used by us may constitute a dimer of the protein described by Bühler and Kägi⁷. Kägi and Vallee¹⁰ previously described an equine protein containing cadmium and zinc with a molecular weight of about 10,000, but they do not discuss the possibility of dimer generation.

We believe that these cells are well suited for the study of induction of cadmium-binding proteins and their biological role, including the possible correlation between Cd resistance and content of Cd-binding proteins.

Ricin resistance in baby hamster kidney cells

LITTLE is understood about the function of the complex oligosaccharide side chains present in cell membrane glycoproteins. One approach to this problem has been to select from cultured mammalian cells variants deficient in cell surface binding sites for certain plant lectins, since in these cells some part of the membrane glycoproteins' carbohydrate moieties should be missing or altered. Such variants have been isolated from Chinese hamster ovary (CHO) cells using ricin¹ (from *Ricinus communis* seeds) and phytohaemagglutinin² (from *Phaseolus vulgaris*), cytotoxic lectins which bind to membrane glycoprotein galactose and N-acetylgalactosamine groups^{3–5}.

We describe here 22 clones of the baby hamster kidney cell line, BHK 21 C13 (ref. 6) resistant to ricin, several of which seem to be deficient in cell surface ricin binding sites.

In our studies BHK cells (approximately 2×10^5) growing in Glasgow modified minimal essential medium (MEM) plus 10% foetal bovine serum (FBS) at 33°C on 60-mm Falcon plastic dishes were treated with methyl-N-nitro-N-nitrosoguanidine

(0.5 $\mu\text{g ml}^{-1}$) for 1 d. Surviving cells (about 28% of the total) were grown for a further 4 d to establish mutant phenotypes, trypsinised and replated at 5×10^5 cells per dish in MEM plus 2% FBS. Since FBS contains ricin-binding glycoproteins the lower concentration was used in the selection procedure. The cells were grown to approximately 3×10^6 per dish at 39 °C, ricin (0.2 μg or 1 $\mu\text{g ml}^{-1}$) was added and incubation continued for 7–10 d in the presence of ricin with the medium changed every 3 d. In some experiments the ricin concentration was increased from 0.2 μg to 1 $\mu\text{g ml}^{-1}$ after the first 3 d. Many

Fig. 1 Lactoperoxidase-catalysed surface iodination of baby hamster kidney (BHK) cells. Intact cells of normal BHK cells and the ricin resistant variant Ric^R14 were iodinated with ¹²⁵I by standard lactoperoxidase labelling techniques. The iodinated cells were dissolved in hot sodium dodecyl sulphate plus 2-mercaptoethanol and examined by slab gel polyacrylamide gel electrophoresis. The radioiodinated bands represent surface components accessible to lactoperoxidase, an enzyme that does not penetrate the plasma membrane of intact cells to label cytoplasmic proteins or glycoproteins. The bands were detected (top panel) by autoradiography or by (lower panel) cutting up the gel into 2-mm slices and counting in a Wallac gamma spectrometer. Approximate molecular weights of proteins were estimated by reference to the mobilities of reovirus structural proteins¹⁵. *a*, Normal cells at confluence; *b*, ricin-resistant cells Ric^R14 at high cell density (confluence). Note the appearance of a major iodinated band of apparent molecular weight 250,000 in the normal and Ric^R14 cells at confluence. Note the enhanced mobility of the other iodinated bands present in Ric^R14 cells relative to the corresponding iodinated components of the normal BHK cells.

Table 1 Selection, resistance and ricin binding sites of ricin-resistant BHK cell clones

Cells	Ricin concentration for selection	Relative plating* efficiency (± ricin)%	Relative binding† of ¹²⁵ I-ricin
Normal	—	1–2	1.0
Ric ^R 1	0.2 $\mu\text{g ml}^{-1}$	35	1.12
2	0.2 $\mu\text{g ml}^{-1}$	25	1.12
3	0.2 $\mu\text{g ml}^{-1}$	2.5	ND
4	0.2 $\mu\text{g ml}^{-1}$	ND	ND
5	0.2 $\mu\text{g ml}^{-1}$	17	ND
6	1 $\mu\text{g ml}^{-1}$	60	0.15
7	1 $\mu\text{g ml}^{-1}$	83	0.43
8	1 $\mu\text{g ml}^{-1}$	91	ND
9	1 $\mu\text{g ml}^{-1}$	50	0.12
10	1 $\mu\text{g ml}^{-1}$	40	0.13
11	1 $\mu\text{g ml}^{-1}$	83	ND
12	1 $\mu\text{g ml}^{-1}$	43	1.36
13	1 $\mu\text{g ml}^{-1}$	75	ND
14	0.2 $\mu\text{g ml}^{-1}$	43	0.12
15	then 1.0 $\mu\text{g ml}^{-1}$	107	0.14
16	1.0 $\mu\text{g ml}^{-1}$	50	1.05
17	1.0 $\mu\text{g ml}^{-1}$	35	0.27
18	1.0 $\mu\text{g ml}^{-1}$	70	0.47
19	1.0 $\mu\text{g ml}^{-1}$	70	1.97
20	1.0 $\mu\text{g ml}^{-1}$	51	0.19
21	1.0 $\mu\text{g ml}^{-1}$	83	0.10
22	0.2 $\mu\text{g ml}^{-1}$	40	1.5
	then 0.5 $\mu\text{g ml}^{-1}$		

* Trypsinised cells in Ham's F10 medium plus 10% foetal calf serum were plated on 60-mm Falcon dishes at approximately 1,000 cells per dish. After 1–2 h at 39 °C ricin was added at 0.1 $\mu\text{g ml}^{-1}$ final concentration and after further incubation for 7–10 d, cell colonies were stained with 1% gentian violet in 20% ethanol and counted. The relative plating efficiency is the number of colonies developed in the presence of ricin compared with the number of colonies developed in the absence of ricin from equal numbers of cells.

† Cells growing on 35-mm diameter plastic dishes were rinsed with warm phosphate-buffered saline. Serial dilutions of a solution of lactoperoxidase-catalysed, ¹²⁵I-labelled lectin (usually at least 10⁷ c.p.m. mg⁻¹ of protein) were added (each 1 ml). After incubation at room temperature for 60 min the cells were rinsed several times to remove unbound lectin, dissolved in alkali and assayed for cell protein and ¹²⁵I radioactivity. Binding curves were treated as Scatchard plots to obtain the total number of binding sites per cell. Values are expressed relative to normal BHK cells. The number of ricin binding sites for normal BHK cells is 5.6×10^6 per cell.

cells detached from the plastic surface and were removed during the changes of medium. Colonies surviving at a frequency of approximately 10⁻⁶ in ricin (1 $\mu\text{g ml}^{-1}$) were removed by trypsinisation under sterile glass cloning cylinders, transferred to Falcon dishes containing ricin-free fresh Ham's F10 medium containing 10% FBS, and grown to high densities to establish cell lines which thereafter were cultured in MEM plus 10% FBS. No surviving colonies were obtained from non-mutagenised cells treated with ricin at 1 $\mu\text{g ml}^{-1}$.

All of our clones except one (Ric^R3) retain a substantial degree of their resistance when cultured in the absence of ricin (Table 1), even for 1 yr, and therefore exhibit stable heritable alterations. Resistance to ricin is expressed equally at both 33 °C and 39 °C, and thus no clone exhibits temperature-sensitive resistance, which we had hoped our selection method would provide. Of the 22 resistant clones several of those tested, for example Ric^R1, 2, 12, 16, 19, bind about as much or more ricin as do normal sensitive BHK cells (Table 1). It is likely that in these cells resistance is mediated by either a lack of endocytosis of bound lectin⁷ or an inability of the lectin once in the cytoplasm to affect protein synthesis^{8,9}. Other resistant clones, however, are deficient (Table 1) in ricin binding sites, for example, Ric^R9, 14, 15, 21.

Ricin-resistant clones deficient in lectin binding sites are probably defective in biosynthetic steps involved in their assembly. An example of such a step is the addition of N-acetylglucosaminyl residues to the internal mannose core of growing oligosaccharide side chains of surface membrane glycoproteins terminating in the sequence sialyl-galactosyl-N-acetylgluco-

saminyl-mannose¹⁰. Clones of CHO cells deficient in binding sites for phytohaemagglutinin and ricin, respectively, are deficient in a β -N-acetylglucosaminyl transferase^{11,12}, and presumably cannot transfer N-acetylglucosamine or the penultimate galactose to those glycoprotein oligosaccharides necessary for lectin binding. Enzymatic analysis of cell extracts of some of our ricin-resistant BHK clones which are deficient in binding sites, that is Ric^R14, 15, 18 and 21, has indicated that Ric^R14, but not the others, has less than 10% of normal β -N-acetylglucosaminyl transferase activity when neuraminidase, β -galactosidase and β -N-acetylglucosaminidase-treated α_1 -acid glycoprotein is used as acceptor¹³. The activities of sialyl and galactosyl transferases in all these clones, including Ric^R14, assayed using the appropriate derivatives of the α_1 -acid glycoprotein are similar to normal BHK cells. It is possible, of course, that small differences in specific glycosyl transferases, for example, a galactosyl transferase, cannot be detected or that α_1 -acid glycoprotein derivatives are not suitable acceptors for all transferases, or simply that the biosynthetic block lies elsewhere, for example, N-acetylgalactosaminyl transferase.

Additional evidence that our ricin-resistant clones deficient in binding sites are blocked at some stage of carbohydrate chain assembly comes from surface labelling. Several surface components of normal BHK cells are labelled by ¹²⁵I-iodination catalysed by lactoperoxidase (Fig. 1). In clones Ric^R14 (Fig. 1), Ric^R7, Ric^R15 and possibly Ric^R21 (not shown) the radioactive bands move more rapidly during polyacrylamide gel electrophoresis than the radioactive bands of normal cells, which is consistent with the surface glycoproteins of these clones being less well glycosylated. In contrast, the surface glycoproteins of Ric^R16 and Ric^R19, resistant clones not deficient in ricin binding sites (Table 1), show no increase in migration on polyacrylamide gels (R.N., unpublished). It is interesting that the large iodinated glycoprotein of apparent molecular weight 250,000, described by others in various cells¹⁴, is present in normal BHK cells and in the Ric^R14 clone (Fig. 1) when the cells are at high density, and that the mobility of this large glycoprotein apparently does not change in the ricin-resistant clone. Either this large glycoprotein does not bind ricin and is unaffected by the glycosylation defect, or the carbohydrate is a minor part of the whole molecule and decreased glycosylation is not detected by our method.

Further evidence for premature termination of glycoprotein oligosaccharides in our clones deficient in ricin binding sites comes from binding studies with the lectin concanavalin A (con A) with specificity for mannosides. In clones Ric^R14, 15 and 21 the number of ¹²⁵I-con A binding sites is increased 1.5–3.0-fold, suggesting increased exposure of terminal mannose groups.

We conclude therefore that stable alterations in surface glycoprotein oligosaccharides can be selected for in BHK cells. We have isolated clones which bind ricin poorly due presumably to a loss of surface galactose or N-acetylgalactosamine, and in one case (Ric^R14) we have demonstrated an enzyme deficiency in a β -N-acetylglucosaminyl transferase which could lead to such a loss. The alterations to surface glycoprotein oligosaccharides seem, however, to have negligible effects on the normal growth processes of our variants. Nevertheless, the availability of stable variants of BHK cells showing altered carbohydrate structure will be useful in studies of the role of surface carbohydrates in intercellular properties such as adhesion—several of our variant cells, particularly Ric^R14, show weaker adhesion to plastic culture surfaces—and metabolic cooperation.

Liquid-crystalline characteristics of the thick filament lattice of striated muscle

THE lattice of thick filaments (A-band lattice) in striated muscle is similar in many respects to smectic liquid-crystalline structures in which macromolecules are arranged parallel to and equidistant from each other forming lattice planes^{1,2}. Like other liquid-crystalline systems, this lattice may exist in two characteristic conditions which are determined either by a simple balance between electrical forces^{3–5,7} or subject to an additional volume-limiting force^{6–8}. Some mathematical analyses^{2,4–6,9–12} agree with the experimental results obtained

Fig. 1 A-band volume of muscle as a function of osmolarity. The relative volume of the A-band in living crayfish muscle fibres is plotted against the reciprocal osmolarity of sodium chloride media. The A-band volume across the whole fibre was determined from the optically measured diameter of the fibre at a constant sarcomere length and the dimensions of the thick filaments (4.4 μ m). The osmolarity was varied by adjusting the NaCl concentration of the normal medium (NaCl, 200 mmol l⁻¹; CaCl₂, 13.5 mmol l⁻¹; KCl, 5 mmol l⁻¹; Tris, 5 mmol l⁻¹, buffered to pH 7.4).

Fig. 2 Unit-cell area of the thick filament lattice of intact fibres as a function of the A-band volume. The unit-cell area and interfilament distance of the thick filament lattice of crayfish muscle at constant sarcomere length is plotted against the relative A-band volume as determined by the osmolarity of the sodium chloride media (compare Fig. 1). The close approximation of the data to a straight line (fitted by the method of least squares, $r = 0.92$) over a portion of the range indicates a region in which the lattice exhibits the Boyle-van't Hoff pressure-volume relationship of the fibre. In this region the lattice behaviour is similar to that of the volume-constrained liquid-crystal. The ordinate intercept indicates an osmotic dead space. The break in the line at an A-band volume of 135% of the control demonstrates that the unit-cell area of the thick filament lattice no longer follows the A-band volume, indicating that the lattice changes from a volume-constrained to an electrically balanced condition when the thick filament separation reaches approximately 582 Å at a sarcomere length of 9.6 μm .

from glycerinated muscle³ and skinned fibres¹³⁻¹⁵, but are only applicable to the electrically balanced liquid-crystalline condition. The behaviour of the thick filament lattice in intact living muscle cannot be explained exclusively in terms of a balance between Van der Waals' and electrostatic force⁵ because the Donnan-osmotic steady state across the sarcolemma determines the net water flux and thereby controls the fibre and lattice volumes. Cross bridges or M-line bridges cannot be evoked as a mechanism for maintaining the lattice regularity because the array persists in EGTA-relaxed skinned fibres in muscles having no M-line structure¹⁴.

The volume of a single muscle fibre of crayfish (*Orconectes*), and in particular the A-band volume, is a function of the osmolarity of the bathing medium. This is evident from Fig. 1, in which the relative A-band volume across the fibre (optically determined fibre diameter times thick filament length) is plotted against the reciprocal of the osmolarity of the medium. The approximation of the data to a straight line (fitted by the method of least squares, $r = 0.97$) indicates compliance with the Boyle-van't Hoff pressure-volume relationship. In physiological conditions with the usual complement of myofilaments, the fibre volume is less than that necessary for the attainment of a balance between Van der Waals' attractive and Coulombic repulsive forces. The unit-cell volume of the sarcomere (the unit-cell volume of the thick filament lattice extended to the Z-lines) and the thick filament separation of the intact fibre also follows the Boyle-van't Hoff relationship exhibited by the whole fibre¹⁵. Figure 2 shows that the thick filament spacing is a function of A-band volume.

The unit-cell area of the A-band lattice (determined from the 1, 0 X-ray diffraction reflections of single fibres at constant sarcomere length) is plotted against the A-band volume of the whole fibre (determined by the osmolarity of the medium and measured optically). The linear fit ($r = 0.92$) of the data signifies agreement with the Boyle-van't Hoff equation and the ordinate intercept is indicative of an osmotic dead space¹⁵. These data are consistent with volume-constrained liquid-crystalline behaviour in which elongate particles comprising the lattice can be confined to a volume smaller than that which is necessary for an electrical balance¹⁶. Thus, interaxial distance between the particles (d) is inversely proportional to the square root of the particle concentration $[P]$:

$$d \propto 1/\sqrt{[P]} \quad (1)$$

Since particle concentration is inversely proportional to the volume, in the case of muscle the filament spacing within the living fibre is a function of the A-band volume (V_A) to which the thick filaments are confined by the smectic nature of the lattice:

$$d \propto \sqrt{V_A} \quad (2)$$

The explanation is straightforward. When interaxial separation is decreased by reduction of the available volume, the electrostatic repulsive forces which vary exponentially with separation⁹ are enhanced and must necessarily become greater than the Van der Waals' forces which vary inversely as the fifth power of distance⁹. Thus, the interaction energy of the system is

Fig. 3 Comparison of intact and skinned fibre lattice behaviour, recomputed and redrawn from April *et al.*¹⁵. The relative unit-cell areas of fibres in potassium propionate media are plotted against the reciprocal of the relative osmolarity for intact fibres (●) and the corresponding ionic strength for skinned fibres (▲). The lines are fitted by the method of least squares ($r_s = 0.94$; $r_{\Delta} = 0.90$). The open symbols represent mean values with the number of experiments and the standard deviations from the mean indicated. The divergent behaviour of the two lattices below a relative inverse osmolarity (or corresponding A-band volume) of approximately 130% of the control signifies different liquid-crystalline conditions. Above 130%, the behaviour of the intact fibre lattice is similar to that of the skinned fibre, indicating a change in the lattice of the intact fibre from a volume-constrained to an electrically balanced liquid-crystalline condition.

increased. If additional volume becomes available, the filaments move apart uniformly with the additional interaction energy (increased electrostatic forces) responsible for this readjustment. When interfilament distance increases to the point where opposing electrical forces balance, the interaction energy is minimal and further movement ceases unless pH or ionic strength of the medium is altered^{3,7,13,15}.

In other words, the lattice expands to fill the A-band until an equilibrium between Van der Waals' and electrostatic forces is reached.

The volume-limiting effect of the sarcolemma in the living fibre is equivalent to the performance of osmotic work whereby the interaction energy of the system is increased through confinement of the thick filaments to a volume less than that necessary for electrical force balance. It should be noted that in the volume-constrained condition the osmotic pressure counterbalances the electrostatic repulsive forces and relegates the Van der Waals' forces to a minor role in the maintenance of lattice stability. Thus, in the volume-constrained condition representative of living muscle, the fibre volume determines the maximum possible thick filament separation and, thus, the magnitude of the electrostatic forces. Within this confine the electrostatic forces between the thick filaments maintain the hexagonal lattice structure by mutual repulsion.

The volume-constrained liquid-crystalline condition of living single muscle fibres and the electrically balanced liquid-crystalline condition of skinned fibres can be compared in Fig. 3, in which the relative unit-cell areas of the lattices are plotted against the relative osmolarity and corresponding ionic strength of the bathing medium at pH 7.4. Both preparations were in identical media and the change in osmolarity or ionic strength was accomplished by adjusting the potassium propionate concentration of the relaxing solution. Clearly the behaviours of the filament lattices are different. The interaxial spacing in the skinned fibre is sensitive to the ionic strength of the medium whereas the interaxial spacing of the intact fibre is sensitive only to osmotically induced volume changes. In addition, on removal of the sarcolemma from a living fibre in conditions where the external ionic strength matches that of the sarcoplasm, the lattice immediately expands to the dimensions observed for the electrically balanced lattice at that particular ionic strength and pH. This indicates that the physiological volume of the living muscle fibre is inadequate for an equilibrium between van der Waals' and electrostatic forces and that such a condition is achieved after skinning the fibre.

Another inference from the data presented in Figs 2 and 3 is that as the intact fibre swells a point is reached where the filament lattice ceases to expand while the fibre as a whole continues to swell. This point represents a transition from a volume-constrained to an electrically balanced liquid-crystalline lattice because, once this point is reached, the lattice no longer exhibits a volume dependence and the behaviour becomes similar to that of the skinned fibre with respect to changes in ionic strength. Thus by sufficient swelling the volume constraint on the lattice can be removed. From this it follows that the spacing of the lattice in the intact fibre is determined by the condition that it fills the available volume until the spacing is sufficient for Van der Waals' attractions to balance electrostatic repulsion. Consequently, the previous calculations by Elliott *et al.*⁵, from which they concluded that lattice spacing was determined solely by the balance of Van der Waals' and electrostatic forces, cannot be applied to living muscle in physiological solution and their explanation for constant-volume shortening must be incorrect.

The principal conclusion to be drawn is that the thick filament lattice of living muscle is normally constrained and is sensitive only to changes in A-band volume. In contrast, the lattice state of glycerinated muscle, skinned fibres and greatly swollen fibres is electrically balanced *vis-à-vis* van der Waals' attractive and electrostatic repulsive forces and is sensitive to any parameter which affects electrostatic charges.

I thank Donald Wong for discussions. This research was supported by a grant from the US Public Health Service.

Low doses of DNP-D-GL, a potent hapten-specific tolerogen, are immunogenic *in vitro*

THE DNP conjugate of a D-amino acid copolymer of glutamic acid and lysine (DNP-D-GL) is a potent inducer of DNP-specific tolerance *in vivo* and *in vitro*^{1,2}. Simultaneous administration of DNP-D-GL and allogeneic cells to mice, however, results in anti-DNP antibody formation rather than tolerance³. DNP-D-GL thus seems to block activation of DNP-specific precursor cells in ordinary circumstances but to activate cells altered by allogeneic effect factors⁴. We have attempted to define further the conditions in which DNP-D-GL can induce antibody formation, a question made more relevant by the proposal that nucleic acids coupled to D-GL may be useful in preventing autoimmune disease, a situation where induction of antibody formation rather than tolerance would be unfortunate.

We have investigated the conditions in which DNP-D-GL can act as a tolerogen or an immunogen for T-independent anti-DNP responses of mouse spleen cells *in vitro*. Nanogram quantities of DNP-D-GL induced anti-DNP antibody formation, while larger amounts prevented responses to DNP-conjugates, as previously reported². Presentation of the DNP-D-GL in the form of antigen-pulsed macrophages further increased its immunogenicity and (or) decreased its tolerogenic potential. DNP-D-GL-induced anti-DNP antibody in nude mouse spleen

Fig. 1 The anti-DNP antibody response of BALB/c spleen cells cultured *in vitro* with DNP₇₅-D-GL. ○, Continuous DNP-D-GL added to normal spleen cells; ●, spleen cells exposed to indicated concentration of DNP-D-GL, washed, and antigen-pulsed adherent cells prepared. Normal non-adherent cells were added to the DNP-D-GL-pulsed adherent cells. △, Continuous DNP-D-GL added to macrophage-depleted non-adherent cells.

cell cultures. We conclude that DNP-D-GL is not intrinsically tolerogenic but can deliver both activating and inactivating signals to B lymphocytes, and that it is the concentration of DNP-D-GL and (or) the form of presentation which determines which of the two signals is dominant.

Spleen cells from BALB/c mice or from NIH outbred homozygous and heterozygous nude mice were cultured in Mishell-Dutton conditions as previously described⁶. DNP₇₅-D-GL (75 mol DNP per 105,000 daltons average molecular weight of D-GL, G:L ratio of 60:40) was added to cultures to give final concentrations from 10^{-8} to 10^4 $\mu\text{g ml}^{-1}$. DNP-D-GL-pulsed macrophages were prepared by incubating spleen cells with antigen for 1 h at 4 °C, washing three times, plating in culture dishes for 1 h at 37 °C, and washing the adherent cells twice more. Direct plaque-forming cells (PFC) were counted using TNP-coupled sheep erythrocytes⁶ as indicator cells. Induction of DNP-specific tolerance *in vitro* was assayed by the simultaneous addition of 10^{-3} $\mu\text{g ml}^{-1}$ DNP₃₉-aminoethylcarbonyl-methyl (AECM)-Ficoll, a thymus-independent antigen *in vitro*⁶. Both DNP₇₅-D-GL and DNP₃₉-AECM-Ficoll were endotoxin-free by the *Limulus* amoebocyte lysate gelation assay⁷. Specificity of tolerance induction was shown by lack of depression of *in vitro* responses to sheep erythrocytes.

Figure 1 shows the mean anti-DNP response in three replicate experiments of spleen cells cultured with DNP₇₅-D-GL in three conditions: soluble antigen presented continuously to normal spleen cells; antigen-pulsed adherent cells (>90% macrophages) mixed in a 1:20 ratio with normal non-adherent (macrophage-depleted) spleen cells; or soluble antigen added directly to non-adherent cells. Soluble DNP-D-GL induced substantial anti-DNP-PFC on the part of whole spleen cell populations but failed to induce any detectable responses in non-adherent spleen cells. DNP-D-GL pulsed macrophages,

however, stimulated quite marked anti-DNP responses by non-adherent spleen cells. Since the amount of antigen retained by pulsed adherent cells was 1% or less, of the original dose indicated in Fig. 1 (as determined by retention of ³H-DNP-D-GL), the optimal amount of DNP₇₅-D-GL for inducing antibody production was 10^{-3} – 10^{-4} $\mu\text{g ml}^{-1}$ for both soluble antigen and pulsed macrophages.

The effect of immunogenic and suprainmunogenic concentrations of DNP-D-GL on the anti-DNP response of normal spleen cells to DNP₃₉-AECM-Ficoll is shown in Fig. 2. Data are pooled from 22 experiments with each point representing a group mean response in one experiment; the geometric mean \pm s.e. is plotted. Immunogenic concentrations of DNP-D-GL (10^{-4} – 10^{-3} $\mu\text{g ml}^{-1}$) caused an insignificant reduction in the DNP-Ficoll response, but higher concentrations were highly suppressive of anti-DNP responses. This effect was antigen-specific in that parallel control responses to sheep red blood cells were not reduced by DNP-D-GL.

Spleen cells from individual outbred athymic nude mice responded to DNP-D-GL *in vitro* as well as spleen cells from phenotypically normal littermates (Table 1), although both had low anti-DNP PFC responses compared with BALB/c spleen cells (for example, Fig. 1). Nude spleen cells were susceptible to tolerance induction by DNP-D-GL; for example, $1 \mu\text{g ml}^{-1}$ reduced the DNP-Ficoll response from 1,204 to 240 PFC per culture. Induction of both antibody synthesis and DNP-specific tolerance thus seem to occur in mice lacking detectable T cell function.

These results indicate that DNP-D-GL can act as a T-independent antigen as well as a T-independent tolerogen in normal and nude mice. The response to DNP-D-GL does not occur when macrophage numbers are diminished, but it is not yet clear whether the remaining non-adherent lymphocytes are unable to respond to DNP-D-GL or are rendered tolerant by continuous exposure to soluble antigen. We conclude that the

Fig. 2 Inhibition of the anti-DNP response of BALB/c spleen cells to DNP₃₉-AECM-Ficoll by various concentrations of continuous DNP₇₅-D-GL. Each point is the mean response in a single experiment; data are pooled from 22 experiments. Horizontal bars indicate the geometric mean \pm s.e.

poorly metabolisable nature of D-Gl does not make it an obligate tolerogen, at least for normal mouse spleen cells in culture, and that its mechanism of tolerance induction may serve as a useful model for naturally occurring tolerance to antigens such as polysaccharides which display T-independent-like characteristics.

I thank Mrs Barbara Johnson for technical assistance and Dr William E. Paul for helpful discussions.

Continuous production of peroxidase, esterase, alkaline phosphatase and lysozyme by clones of promyelocytes

THE classic description of maturation of cells of the bone marrow myeloid series is based on static observation of morphological and biochemical differences between cells in close proximity¹. It is generally accepted that multipotential stem cells progress under appropriate leukopoietic stimuli to myeloblasts, and then to promyelocytes, myelocytes, metamyelocytes and at least three specific mature populations with distinct biological functions: polymorphonuclear neutrophils, basophils and eosinophils². The stage at which a cell becomes committed to a specific population is unknown. One approach to defining the maturation relationship between myeloid cells has been through study of the production of enzymes³⁻⁵, chemical mediators⁶ and other intracellular or surface proteins⁶⁻⁸ specific to each leukocyte population. Histochemical techniques for identification of myeloid enzyme production have been used to correlate the production of these proteins with different stages of morphological maturation¹⁰. The inability to establish tissue culture lines derived from single myeloid cells stably arrested in development has prevented study of the degree of differentiation of cells in each

stage of maturation. We report here the establishment of multiple clones of rat myeloid cells which maintain stable promyelocyte morphology *in vitro* and produce four enzymes. Clones derived from more primitive myeloblast cells produce only lysozyme.

The Jones chloroma¹¹, a rat leukaemia line passaged more than 50 times *in vivo*, has maintained morphology typical of normal promyelocytes. Bone marrow samples obtained from affected rats are replaced with leukaemic cells which are positive in assays for esterase, alkaline phosphatase, peroxidase and lysozyme; however, fresh leukaemia cell explants or cells grown for short periods in tissue culture demonstrate enzyme positivity in only a fraction of cells tested by each histochemical assay (unpublished results). Similar observations are common when marrow is examined from a wide variety of experimental and human myelogenous leukaemias. This could reflect stable differences in enzyme production by different subpopulations within a leukaemia line or growth cycle-dependent variation in enzyme production by a truly homogenous population of cells. Another leukaemia line, the Wistar/Furth (W/Fu) acute myelogenous leukaemia (AML), has been shown to exhibit more primitive morphology and produce only lysozyme *in vivo* and *in vitro*¹². Here, 5-10% of cells consistently have seemed lysozyme-negative and could represent a subpopulation arrested in a developmental stage before that associated with lysozyme production.

To test these possibilities clonal lines were established in tissue culture from each transplantable tumour. These were maintained *in vitro* for around 2 months and then tested both for enzyme production and for morphological appearance. As Table 1 shows, each of 23 clones of the Jones chloroleukaemia produced peroxidase, esterase, alkaline phosphatase and lysozyme. Fifteen clones of W/Fu AML cells were indistinguishable in myeloblast morphology and production of a single enzyme, lysozyme. The proportion of positive cells in each assay did not differ significantly between clones tested.

Each clone of either line had a similar *in vitro* doubling time of 15-20 h, and saturation density of 3.0×10^6 - 4.0×10^6 cells ml⁻¹ in liquid medium. The clonal lines formed colonies with an efficiency of 5.0-5.5% in either liquid medium or semi-solid medium containing 0.9% methylcellulose. These *in vitro* growth parameters were indistinguishable from those of the parent lines.

The clonal lines were passaged continuously and tested periodically for changes in morphology and enzyme production and for evidence of C-type RNA virus production by assay for reverse transcriptase activity in tissue culture fluids¹³. The virus-specific nature of the enzyme was confirmed by inhibition

Table 1 Enzyme production by clonal lines of myeloid cells

Cell line	No. clones tested	No. clones positive (range of percent cells positive)			
		LAP	Esterase	Enzyme produced Myeloperoxidase	Lysozyme
Jones promyelocytic leukaemia	23	23 (85-91)	23 (90-95)	23 (91-95)	23 (88-95)
W/Fu myeloblastic leukaemia	15	0	0	0	15 (91-96)

Cells were grown in Dulbecco's modification of Eagle's medium supplemented with 10% foetal calf serum (Colorado Serum Co.). The establishment of continuous tissue culture lines of the Jones chloroleukaemia and Wistar/Furth acute myelogenous leukaemia (W/Fu AML) have been reported¹². Multiple clonal lines derived from single cells of each leukaemia were selected by the microtitre plate technique according to published procedures¹⁹. Each was carried in tissue culture for 100 d. Histochemical assay methods for detection of myeloperoxidase, esterase and leukocyte alkaline phosphatase have been described¹⁰. A fluorescent antibody staining technique was used for detection of intracellular lysozyme. Cells were fixed and incubated with pre-absorbed rabbit serum, prepared against purified rat lysozyme, then washed and labelled with fluorescein-isothiocyanate conjugated, goat anti-rabbit globulin. Control preparations were incubated first with normal rabbit serum. Cells were scored using a $\times 1,000$ binocular microscope or fluorescent microscope by counting 1,000 cells in each of duplicate preparations for each clone.

with antibody to mouse C-type virus reverse transcriptase¹⁴. Several clones of the Jones chloroleukaemia were uniformly virus positive after 10 d in culture. The virus produced was shown to be C-type in origin by immunological tests for the interspecies antigenic determinant of the 30,000 molecular weight polypeptide of mammalian C-type virus¹⁵, and by electron microscopic analysis. It seemed likely that this was an endogenous rat virus. In spite of the continuous production of C-type virus for more than 300 d *in vitro*, there was no detectable change in promyelocyte morphology or in the strength of production of the four myeloid enzymes (data not shown). W/Fu AML cells remained virus-negative for several months in culture in spite of growth characteristics comparable with Jones chloroleukaemia cells. After 150 d *in vitro*, some W/Fu AML clones were found to be producing low levels of an indistinguishable rat C-type virus, yet there was no detectable change in myeloblast morphology or myeloid enzyme production.

Our results provide the first demonstration of the production of multiple lysosomal enzymes by clonal lines of myeloid cells and imply that all myeloid stem cells can produce multiple enzymes. The fact that only one myeloid enzyme was produced by W/Fu AML cells possessing a primitive myeloblast morphology, while several enzymes were synthesised by the more differentiated promyelocytic line, supports the finding in bone-marrow preparations of low or absent levels of myeloid enzymes in morphologically undifferentiated cells. If it is true that production of a single enzyme by a myeloblastic leukaemia results from maturation arrest rather than malignant transformation of a unipotential stem cell destined to produce only one enzyme, then stimulation of maturation of these myeloblasts should lead to production of other enzymes. These studies are in progress.

Both spontaneous¹⁶ and chemical^{17,18} activation of C-type viruses endogenous to murine cells in culture have been demonstrated previously. The present studies indicate that the spontaneous release of C-type virus by myelogenous leukaemias in culture occurred in the absence of any detectable morphological or biochemical alteration.

Spontaneous lymphokine synthesis by human blood mononuclear cells

LYMPHOCYTES, after antigenic stimulation, may synthesise and release biologically active soluble factors other than antibodies. These mediators were termed lymphokines by Dumonde¹, and the most extensively studied and best characterised are migration inhibitory factors which can inhibit the migration of macrophages or leukocytes: this is the property used for their *in vitro* bioassay. Apart from antigens, various other stimuli may trigger lymphokine synthesis by lymphocytes, for example, polyclonal mitogens², anti-immunoglobulin or membrane Fc or C3-receptor reactions^{3,4}. Furthermore, migration inhibitory activity has been found in the long term culture supernatants of some established lymphoid and even non-lymphoid cell lines^{5,6}. We report here that human blood mononuclear cells can, apparently without any inducing agent, produce material inhibiting migration of homologous leukocytes.

Mononuclear cells from healthy human individuals were obtained by Ficoll-Isopaque centrifugation of heparinised peripheral blood⁷, or by incubating sedimented leukocytes for 30 min. at 37 °C with carbonyl iron and removing the phagocytic cells with a magnet. If not otherwise stated, 2×10^6 cells were cultured in 'universal' polystyrene containers (Sterilin, Richmond, Surrey) for 3 d in 1 ml of HEPES-buffered (10 mM) tissue culture medium 199 supplemented with 10% inactivated horse serum. Penicillin (70 IU ml⁻¹), streptomycin (70 µg ml⁻¹) and bicarbonate (0.1 M) were added to the medium, final pH 7.4. When puromycin was added to the control tubes its concentration was 5 µg ml⁻¹, which in previous tests was found to block the synthesis of migration inhibitory activity by cultured phytohaemagglutinin-stimulated cells. This concentration did not inhibit the effect of migration inhibitory activity on leukocytes and caused 10.7% inhibition of the migration of normal leukocytes in direct tests. The cell-free culture supernatants were tested for the presence of migration inhibitory activity with normal human blood leukocytes by the method of Clausen⁸. Each supernatant was tested in five or six replicate determinations. In our hands this method worked with standard deviations ranging from 2.2 to 11.8%, mean 6.6%.

In a series of experiments with mononuclear cells from 18 individuals, supernatants from unstimulated cultures produced 12.8% (mean) inhibition of migration when compared with migration areas of leukocytes in the corresponding medium. The phenomenon was not constant as significant inhibition (*t* test, paired samples) occurred in 11 out of 18 supernatants. In those 11 individuals the mean percentage of inhibition was 21.2 and the range was from 13.5 to 28.3%. That this was due to material actively synthesised by cultured cells is demonstrated in Table 1. The phenomenon did not occur if protein synthesis was blocked by cold or puromycin. The fact that, in the presence of puromycin, areas of migration were 9% smaller than in controls is explained by the direct effect of puromycin on leukocyte migration. Therefore, the use of puromycin controls in later experiments results in under- rather than overestimation of migration inhibitory activity.

Obviously, something in the conditions in which the cells remained during culture could stimulate the cells and bring about the synthesis of lymphokines. For example, foetal calf serum has been shown to be mitogenic for mouse B cells⁹. Therefore media supplemented with horse serum or autologous serum or no serum were compared for their possible stimulating activity (Fig. 1). The culture supernatants contained migration inhibitory activity regardless of the presence or nature of serum. Autologous serum did not affect inhibition. This indicates that

Table 1 Effect of blocking of protein synthesis on the generation of migration inhibitory activity in unstimulated culture supernatants

antibodies were not responsible for the occurrence of this phenomenon.

It is possible that the cells were stimulated during isolation and preparation before culture. Heparin was an unlikely stimulant because the phenomenon was also noticed in cultures of cells originating from blood samples defibrinated using glass beads. Another possibility was Ficoll-Isopaque. To investigate this question we separated mononuclear cells by Ficoll-Isopaque centrifugation, by the carbonyl iron method and by a combination of both. The results (Fig. 2) suggest that the stimulation takes place even in cultures not exposed to Ficoll-Isopaque.

The nature of the cells responding in those conditions was investigated by separating mononuclear cells by the sheep red

Fig. 1 The role of serum as a possible cell stimulating agent. blood cell-rosette technique¹⁰ into T cell-rich and B cell-rich populations. Preliminary experiments suggest that migration inhibitory activity is absent in T cell-rich cell supernatants and the responding cells are B cells and/or monocytes.

We have shown that this lymphokine-like activity in the supernatants of unstimulated cell cultures is brought about by an active synthetic process of cells and that its biological effect is indistinguishable from that of the migration inhibitory lymphokine. We have, however, no chromatographic data to support the conclusion that the phenomenon is caused by a definite migration inhibitory lymphokine. The synthesis of lymphokine(s) by apparently unstimulated human mononuclear cells in conventional culture conditions could be explained in several ways. First, the cells could have been stimulated already *in vivo* although, in our opinion, this is unlikely. Second, in theory, any of the steps in the isolation and preparation of cells could provide the necessary stimulus for the activation of cells. For example, guinea pig spleen B cells, after isolation on a nylon wool column can produce a chemotactic lymphokine without further stimulation⁴. Our experiments have failed so far to prove that any of the substances or procedures we used could act as a cell activating stimulus. Third, these cells may be activated during culture by the surface of the culture vessel on which they settle.

It has become popular to separate B and T lymphocytes and investigate their responses to mitogens, antigens or other

stimuli. In view of the various mechanisms of cooperation or amplification in the response of lymphocytes to these agents, our findings of mediator synthesis by a proportion of the mononuclear cells without evident stimulus should warrant careful interpretation of the claims of B or T cell specificity of various stimuli.

Anti-C3 antibodies in neonatal saliva

ANTIBODIES which react with bound complement components, in particular the third component C3, have been found in the parotid saliva of most normal subjects¹. These antibodies have several unusual properties². Their binding to complement is dependent on calcium ions, they can be inhibited by small amounts of native C3 and although they belong to the IgA class they are macromolecules with a sedimentation coefficient greater than 19S. The titres in mixed saliva are substantially lower than in parotid saliva¹ and the reduction in titre results from the presence of C3 in mixed saliva that combines with the antibody and neutralises its activity. While investigating the possibility that crevicular fluid was the source of C3 in the mouth, we examined samples of saliva from newborn babies. High antibody titres were found in these samples. We report here on the prevalence and properties of this antibody in neonatal saliva.

Whole saliva was collected from 36 babies, 21 male and 15 female, between 30 min and 4 h after birth and before the first milk feed. The saliva sample was collected by means of a small sterile sponge placed in the mouth between the gum and the cheek. The sponge was removed after a few minutes, weighed and mixed with a known volume of saline. After centrifugation the supernatant was separated and stored at -20°C . Antibody activity to complement was determined by a direct agglutination technique using sheep red blood cells coated with human serum¹. High agglutinating titres were found in all 36 samples, the mean titre being 1:3,000 (range 1:500–1:8,000). Agglutination of the cells was calcium dependent and could be reversed by addition of EDTA (final concentration 0.01 M).

The properties of this antibody were examined using saliva samples from six babies. Similar properties were found in all samples and these are summarised in Table 1. Fractionation of saliva on Sephadex G200 revealed that the activity was localised to the void volume fractions, indicating that the molecular weight of this antibody was greater than 10^6 .

Agglutination of complement-coated cells by antibody could be inhibited by small amounts of serum, by purified C3 and by a mixture of the C3 products, C3c and C3d. The inhibitory activity of the C3c and C3d mixture remained unaltered after heating at 56°C for 30 min (conditions which abolish the antigenicity of the C3d fragment)³. Some activity against the C3d fragment could be demonstrated by using the red cells obtained from a patient with cold agglutinin disease; these cells were agglutinated at low titre (1:2–1:8) by half of the neonatal saliva samples tested.

Inhibition by N-acetyl-D-glucosamine	—
Inhibition by mercaptoethanol	+++

+++ , Strong; + , weak; — , absent.

The concentration of IgA in saliva begins to rise a few days after birth^{4,5}. Very little information is available, however, on the concentration of immunoglobulin in saliva collected within a few hours of birth. The concentration and class distribution of immunoglobulin in neonatal saliva was, therefore, determined in 14 samples using a modified radial immunodiffusion assay. This was performed as described previously⁶ except that mono-specific anti-immunoglobulin sera were incorporated into 0.8% 1-mm thick agar plates at a dilution of 1 in 80 and the samples were placed in 3-mm wells and allowed to react for 48 h at 37°C . The lowest detectable concentrations by this method were $2\text{ }\mu\text{g ml}^{-1}$ for IgG and IgM and $1\text{ }\mu\text{g ml}^{-1}$ for IgA. IgM and IgG were present in all unconcentrated samples of neonatal saliva. IgA, however, was detectable in only five of the 14 samples. The mean values and concentration range of the three immunoglobulins in saliva are summarised in Table 2. The distribution of the anti-C3 antibody within the immunoglobulin classes was determined using purified antibody. Pooled neonatal saliva (20 ml) was incubated with complement-coated red cells and after washing, the antibody was eluted from the cell surface by 0.01 M EDTA. The eluate was further concentrated tenfold by ultrafiltration and the concentration of immunoglobulin was determined by radial immunodiffusion. IgA was the only immunoglobulin detectable in the concentrated eluate.

The antibody titres found in neonatal saliva are three to five times higher than the titres found in the parotid saliva of normal adults. The molecular weight, immunoglobulin class and properties of both of these antibodies, however, seem to be identical. Both antibodies are also readily inhibited by native C3, a finding which contrasts markedly with the specificity shown by the serum antibodies which react with fixed complement. Serum immunoglobulins react with the hidden determinants in the complement molecule that are exposed on fixation and they are only weakly inhibited by native C3, whereas salivary antibodies react with the antigens present on native C3. It has been suggested that the anti-C3 antibodies in saliva arise following immunisation, possibly with bacteria which cross react with native C3 (ref. 7). The presence of very high titres in neonatal saliva within a few hours of birth, at a time when bacterial colonisation of the mouth is only beginning to take place⁸, suggests, however, that these antibodies are not produced by the foetus in response to immunisation with oral bacteria. The finding of this antibody in amniotic fluid at 34 weeks supports this view (unpublished results).

Table 2 Concentration of IgG, IgA and IgM in neonatal saliva

	IgG	IgM	IgA
Number positive	14/14	8/8	5/14
Mean ($\mu\text{g ml}^{-1}$) \pm s.e.	14.2 ± 4.5	4.75 ± 1.2	$3.8 \pm 2.0^*$
Range	2–64	2–10	1–11

* Mean of five positive samples.

Attention has already been drawn to the possible relevance of these antibodies to the understanding of the nature of immunological tolerance⁷. Their occurrence in saliva implies that a population of B cells persists during foetal development and continues to survive into neonatal and adult life. The reasons for the persistence of the cells in salivary tissue are not

known but may be related to local factors or possibly to their requirement for calcium ions before binding to C3 occurs.

We thank Dr L. Stimmler for allowing us to study infants under his care.

Antisera to human B-lymphocyte membrane glycoproteins block stimulation in mixed lymphocyte culture

HUMAN B cells are frequently differentiated from T cells by the ready demonstration of immunoglobulin (Ig) on their surfaces¹. In the mixed lymphocyte reaction (MLR) the responding cells are mainly T cells²⁻⁴, whereas B cells have been suggested to be the primary stimulating cells⁵. The effect on the MLR of a specific anti-B-cell serum is therefore of considerable interest. Here we describe rabbit antisera to membrane glycoproteins of cultured human B cell lines which react only with Ig-bearing peripheral blood lymphocytes and which completely block the MLR *in vitro*.

During attempts to make xenoantisera to HL-A antigens, rabbits were immunised with papain-solubilised HL-A antigens purified from the human B cell line RPMI 4265 by previously reported techniques^{6,7}. Subsequently, the antisera were examined to determine the nature of the membrane molecules with which they reacted. The method of analysis involved incubating these antisera with detergent-solubilised membranes⁷ from cultured human lymphoblastoid lines (labelled with radioactive amino acids^{8,9}), precipitating the immune complexes with goat anti-rabbit IgG, and subjecting the washed precipitates to acrylamide gel electrophoresis in the presence of sodium dodecyl sulphate (SDS)⁸. When tested against solubilised membranes derived from B cell lines (in this case, Ig-secreting lines), two of the sera reacted with molecules with apparent molecular weights of 35,000 and 27,000, in addition to what we presumed were HL-A glycoproteins (43,000) and β_2 -microglobulin (11,000)^{7,9-12}. When the sera was tested with labelled material from a human cell line (HSB) with T cell characteristics^{13,14}, however, only 43,000 and 11,000 molecular weight peaks were evident. Figure 1a shows profiles obtained on SDS-gel electrophoresis of a mixture of two immune precipitates. One was formed by incubating one of the sera (serum C) with ¹⁴C-amino acid-labelled, detergent-solubilised membranes from HSB, and the other by incubating serum C with ³H-amino acid-labelled membranes identically solubilised from the cell line SB. SB is an Ig-secreting cell line derived from the same donor as HSB^{13,14}. The additional molecules detected in the SB preparation can be seen clearly. The species with molecular weights 35,000 and 27,000 can also be precipitated from soluble membranes of B cell lines labelled with ³H-glucosamine, under conditions where β_2 -microglobulin (known not to contain carbohydrate¹⁵) is not labelled^{6,7}. This suggests that the molecules on B cell lines are glycoproteins.

In an attempt to make a specific reagent against these

Fig. 1 SDS-gel electrophoresis profiles of immune precipitates of ¹⁴C-amino acid-labelled HSB membranes solubilised in 0.1% Nonidet P-40 (NP-40), 0.15 M NaCl, 0.01 M Tris, pH 8.0 (○), and ³H-amino acid-labelled SB membranes similarly solubilised (●). *a*, A mixture of precipitates formed with each preparation and serum C unabsorbed, *b*, a mixture of precipitates formed with each preparation and serum C absorbed three times (30 min, 25 °C) with 25×10^6 HSB cells per 100 μ l of serum. Insoluble material was removed from detergent-treated membranes¹⁻⁷ by centrifugation at 100,000g for 90 min. An aliquot (25 μ l) of solubilised membranes (200,000 c.p.m.) was incubated with 1.5 μ l of serum for 1 h at 25 °C, and an excess of goat anti-rabbit IgG (adjusted to 0.1% NP-40) was added to effect precipitation. After 30 min at 37 °C, and a minimum of 1 h at 4 °C, the precipitates were washed three times with 0.1% NP-40 in 0.15 M NaCl, 0.01 M Tris, pH 8.0, twice with water, and subjected to electrophoresis on 13% SDS gels prepared according to Laemmli⁸. The gels were cut into 1-mm slices and counted as previously described^{6,7}. Calibration proteins used in molecular weight estimations were bovine serum albumin (67,000), ovalbumin (45,000), chymotrypsinogen A (25,000) and cytochrome *c* (12,000). The arrows indicate the position of the bromophenol blue marker dye.

glycoproteins, serum C was absorbed extensively with the T cell line, HSB. After absorption the serum failed to precipitate the 43,000 and 11,000 molecular weight peaks from the labelled membrane preparations (Fig. 1b). The reaction of the absorbed serum (serum C_{abs}) with the additional glycoprotein peaks in the SB preparation remained intact.

Serum C_{abs} was also examined for complement-mediated cytotoxicity of peripheral blood lymphocytes (PBL), using the ⁵¹Cr-release assay¹⁶. The results are shown in Fig. 2. Before absorption, serum C was highly lytic for human lymphocytes, giving 80% ⁵¹Cr-release, with a 50% release titre of 1 in 330. After absorption with HSB, approximately 25% ⁵¹Cr-release was observed (with a background release of 10%) to an antiserum dilution of 1 in 200 to 1 in 300. This experiment strongly suggests that the serum C_{abs} is cytotoxic for a minor population of peripheral lymphocytes.

The B cell specificity of the serum was demonstrated by two kinds of immunofluorescence study. In the first experiment, aliquots of PBL were incubated at 0 °C with serum C_{abs}, with a rabbit antiserum to human immunoglobulins (rabbit anti-human Ig, Nutritional Biochemicals), or with a mixture of the two sera. In all three cases both sera were diluted 1 in 5 in phosphate-buffered saline (PBS) containing 5% foetal calf serum with dinitrophenol added to 2.5 mM to prevent capping. Fluorescent cells were counted (at least 50 positive cells per sample) after washing and staining with a goat antiserum

to rabbit immunoglobulins conjugated with fluorescein isothiocyanate (FITC-goat anti-rabbit Ig, Meloy Laboratories). PBL treated with serum C_{abs} gave 18.5% positive fluorescence, those treated with rabbit anti-human Ig gave 16.6% positive fluorescence, and cells treated with a mixture gave 17.7% positive fluorescence. No summation was observed with the antiserum mixture, suggesting that both were reacting with the same population. Cells treated with a pre-immune bleed of serum C followed by FITC-goat anti-rabbit Ig showed only 1.3% positive fluorescence.

In a second experiment, designed to determine whether Ig-positive cells were lysed by serum C_{abs}, 10⁷ PBL were incubated with 1 ml of the serum (diluted 1 in 30 in PBS, 30 min, 37 °C), centrifuged (1,000g, 5 min), resuspended in and incubated in 1 ml of rabbit complement (30 min, 37 °C). The cells were then applied to a discontinuous Ficoll-Hypaque gradient¹⁷ and centrifuged (2,000g, 30 min) to remove dead cells. The cells isolated from the interface (greater than 95% viable by Trypan blue staining) were washed and incubated with rabbit anti-human Ig or normal rabbit serum, followed by FITC-goat anti-rabbit Ig as described above. Lysed cells showed 1.7% positive fluorescence with normal rabbit serum and 2.5% positive fluorescence with rabbit anti-human Ig. Cells treated identically, but with normal rabbit serum and complement, showed 2.4% positive fluorescence with normal rabbit serum and 13.4% positive fluorescence with rabbit anti-human Ig. This experiment clearly shows that most (if not all) of the minor population of PBL lysed by serum C_{abs} are Ig-positive, that is, B cells.

Rabbit antisera to human β_2 -microglobulin (β_2m) have been reported to block the MLR in humans¹⁸, as have alloantisera to HL-A antigens^{19,20}. We have been conducting MLR blocking experiments with a rabbit antiserum to β_2m (ref. 7) and another to purified HL-A antigens solubilised by papain (serum A). These antisera react only with the 11,000 and 43,000 molecular weight HL-A-related species when assayed on B cell line labelled membranes by immune precipitation and SDS-gel electrophoresis as described in Fig. 2. These sera and serum C_{abs} were assayed for their ability to block the MLR. Figure 3 shows the results of these experiments. Clearly serum C_{abs} is the most effective at blocking the MLR. The response is reduced to background levels even at a dilution of 1 in 16,000 and is still approximately 50% inhibited at a dilution of 1 in 10⁶. Taking

Fig. 2 Lysis of peripheral blood lymphocytes by serum C (●), and serum C absorbed as in Fig. 1 with the T cell line HSB (○). Dilutions of the sera (10 μ l) were incubated (30 min, 37 °C) with 10 μ l of dextrose-gelatin veronal buffered saline (Grand Island Biological) containing 2 \times 10⁴ PBL (prepared by the method of Boyum¹¹) labelled with Na⁵¹CrO₄ (ref. 16). Rabbit complement (10 μ l) was added and the cells incubated for a further 30 min at 37 °C. After addition of 50 μ l of PBS containing EDTA (15 mM) and centrifugation, aliquots of the supernatants were counted. One hundred per cent release is the total c.p.m. incorporated into 2 \times 10⁴ cells, and the dashed line indicates the ⁵¹Cr-release (10%) when no antiserum was added.

Fig. 3 Effect of various sera on the mixed lymphocyte response: serum C absorbed with HSB (●); serum A, a rabbit anti-HL-A (papain-solubilised) serum (○); rabbit anti- β_2 -microglobulin (■). Controls indicated are: responder cells plus stimulator cells in the absence of rabbit serum (□); responder cells alone (▲); responder cells plus stimulator cells with serum C pre-immune bleed at a dilution of 1 in 64 (△). Vertical bars indicate the standard error of the mean. Stimulator cells were treated with mitomycin C (40 μ g/10⁷ PBL ml⁻¹) for 30 min at 37 °C. One way mixed lymphocyte cultures were set up in quadruplicate in U-well plates (Cooke Engineering). Responder cells (10⁵ per well) and stimulator cells (10⁶ per well) were incubated in 0.2 ml RPMI 1640, with 20% human type A serum and penicillin and kanamycin, containing the indicated dilutions of rabbit sera. All sera were heat-inactivated at 56 °C for 45 min. Cultures were collected using a Skatron cell harvester after 6 d at 37 °C in 5% CO₂ in air. ³H-Thymidine (1 μ Ci) was added per well 16 h before collection.

50% inhibition of the incorporation of ³H-thymidine as an endpoint, serum C_{abs} is one to two orders of magnitude more effective in blocking the MLR than rabbit anti-HL-A and anti- β_2m . The unusual shape of the curves for rabbit anti-HL-A and rabbit anti- β_2m seems to result from direct stimulation of the responder cells by the antisera. Controls with only responder cells and serum A or anti- β_2m added (not shown) gave increased ³H-thymidine incorporation at high concentrations of the sera. In similar controls no stimulation was observed by serum C_{abs}.

The fact that a serum which seems to be specific for B cells can block MLR is interesting, and may indicate that B cells are the predominant stimulator cells, as previously suggested⁴. In additional experiments (unpublished) we have shown that pretreatment of mitomycin C-treated stimulator cells with the anti-B-cell serum, followed by washing, blocks the MLR. Pretreatment of responder cells does not. We do not yet know, however, whether the serum reacts with other cells possibly involved in the MLR, such as macrophages, nor can we positively state that the antigens to which serum C_{abs} are directed are totally absent from T cells. They may be only operationally undetectable.

The nature of the papain-derived product which elicited the production of the B-cell-specific antibodies remains to be determined. At least four bands of apparent molecular weights between 20,000 and 32,000 appear on overloaded SDS gels of the antigen preparation used to produce serum C, in addition to the strong 34,000 and 11,000 molecular weight bands usually observed in papain-solubilised HL-A preparations^{5,6}. One or more of these species may be a papain cleavage product of the 35,000 or 27,000 molecular weight molecules. Experiments to characterise the immunogen(s) further are in progress. The possible relationship of the B cell glycoproteins to mouse Ia antigens, which are of similar molecular size²¹ and found

predominantly on B cells^{22,23} (though some are present on T cells²⁴) is also an area to be investigated. Other anti-human B-cell antisera have been reported^{25,26}, but the nature of the target antigens in these cases is unknown. A lytic antiserum specific for B cells with known target antigens promises to be a valuable reagent in human immunological studies.

We thank Dr Linda Gooding for immunofluorescence reagents and advice, Dr Dean L. Mann for cell lines, and Larry Scurlock for technical assistance. We thank Dr D. B. Amos for a critical review of the manuscript. This work was supported by a grant from the US Public Health Service.

Receptor-mediated inactivation of early B lymphocytes

THE interaction of surface immunoglobulin (sIg), the antigen receptor of B lymphocytes, with ligands—whether antigen or anti-Ig antibodies—initiates a series of surface and cytoplasmic events which, depending on the nature of the ligand and the presence or absence of cooperative signals from other cells, has various outcomes (reviewed in ref. 1). Immediately on the binding of a polyvalent ligand to sIg, the complexes redistribute on the cell surface, a contractile event occurs, the complexes are endocytosed and shed from the membrane and eventually new receptors appear on the cell surface¹. This *in vitro* cycle, in the absence of cooperative interactions, does not lead to B cell differentiation into secreting plasma cells, whereas it does so when induced in the proper conditions involving helper cells^{1,2}.

A crucial step in this ligand-induced cycle is the re-expression of new receptors on the cell surface, a process involving protein synthesis and requiring the activity of microtubules¹. It is expected that an interruption at this step, leading to a lack of receptors on the cell surface, would be tantamount to an inactive B cell unable to respond to antigen. We report here the failure of B cells from young mice to re-express sIg after relatively brief exposure to anti-Ig antibodies. This failure denotes a peculiar sensitivity of early B cells to ligand-receptor interaction in the absence of cooperative effects and could readily explain several of the phenomena of unresponsiveness

seen during the neonatal period. It should be noted that B cells from young mice (until about 2 weeks of age) have characteristics different from most adult B cells in that they lack C3 receptors^{3,4}, cap poorly⁴ and bind more labelled anti-Ig antibodies⁴.

The basic experiments consisted of exposing spleen lymphocytes from young (up to 2 weeks after birth) or adult (8-16 weeks) mice to rabbit anti-mouse Ig antibodies (RAMG) for 1 or 24 h, after which the cells were cultured for several days in the absence of RAMG. Surface Ig was detected by immunofluorescence. When RAMG bound to an adult B lymphocyte, sIg-anti-Ig complexes were eliminated within minutes, leaving the cell membrane cleared of sIg. Then, within a few hours of culture in the absence of anti-Ig, the cell restored its sIg, completing the process by 8-24 h later. The B lymphocyte from a young mouse spleen however, did not behave in this way. Depending on the time the cell was exposed to RAMG, the early B lymphocyte restored its sIg poorly or not at all. As Fig. 1 shows, within 1 d of a 1-h or a 24-h RAMG incubation (both of which completely cleared the cell of sIg), most of the original adult B lymphocytes restored their sIg. In contrast, only about half of the early B lymphocytes re-expressed sIg after a 1-h RAMG treatment, and almost none re-expressed it after 24 h of treatment with RAMG.

Since about half of the early B lymphocytes restored their sIg after a single cycle of clearance, it seems unlikely that the sIg initially on the cell surface represented cytoplasmic Ig. To strengthen this conclusion and to test whether early B lymphocytes can ever completely regenerate their sIg, cells of both ages were treated with the proteolytic enzyme Pronase at doses known to eliminate surface Ig, and then observed for the re-expression of sIg. Figure 2 shows that both early and adult B lymphocytes completely regenerated their sIg after with Pronase clearance. Note also for the early cells that a portion treated with Pronase after 24 h of incubation with RAMG did not re-express sIg. This shows that Pronase did not represent some stimulatory activity which might reverse the

Fig. 1 Re-expression of sIg after treatment with RAMG (the RAMG used was a poly-specific rabbit anti-mouse Ig antibody previously shown to bind only to B lymphocytes in the mouse spleen). Young (6-9 d, *a*) or adult (2-4 months, *b*) C57BL/6 mouse spleens were teased into Hanks' balanced salt solution (HBSS) plus 1% HEPES plus 5% foetal calf serum and washed three times. They were then exposed at a concentration of 10^7 cells per ml to Mishell-Dutton medium¹⁵ alone or containing RAMG ($200 \mu\text{g ml}^{-1}$) for 1 h or 24 h at 37°C in a 5% CO_2 atmosphere. The dose of RAMG was one that totally cleared the cells of sIg. After the RAMG treatments, cells were washed five times, resuspended at 10^7 cells per ml in fresh medium and cultured for various times. For immunofluorescence the cells were washed once, pelleted, resuspended in $50 \mu\text{l}$ of medium and $50 \mu\text{l}$ of fluoresceinated RAMG (FITC-RAMG) ($500 \mu\text{g ml}^{-1}$, F.P. ratio approximately 6:3). The cells were incubated for 30 min at 4°C , washed twice, resuspended 10^7 per ml, and live cells were scored in a Lertz fluorescence microscope. —, Control; ---, 1-h RAMG; - - -, 24-h RAMG

Young and adult C57BL/6 cells were incubated for 1 or 24 h in Mishell-Dutton medium containing RAMG (200 µg ml⁻¹) or no RAMG. They were then washed five times in HBSS plus HEPES plus FCS and resuspended to 10⁶ per ml in RPMI-1640 with penicillin and streptomycin and 5% FCS and 2 mM L-glutamine alone or with LPS (10 µg ml⁻¹). Each point was done in triplicate. After 24 h of culture in 5% CO₂, each tube was pulsed with 1 µCi in 50 µl of ³H-thymidine (2 Ci mmol⁻¹). The incorporation of the labelled thymidine into trichloroacetic acid-insoluble material was determined 24 h later. The results are expressed as the arithmetic mean of triplicate cultures ± s.e.m. E-C, Experimental mean—control mean; E/C, experimental mean/control mean.

effects of the 24-h treatment with RAMG. The main conclusion from the Pronase experiments is, therefore, that early B lymphocytes can re-express their sIg as completely and as rapidly as adult B lymphocytes but are specifically inactivated by interaction with RAMG.

The next question asked was whether these early B lymphocytes were inactivated or totally deleted from the cultures (that is, killed). To determine this, the spleen cells were examined after exposures to RAMG for the presence of another⁵,

Fig. 2 Re-expression of surface Ig after treatment with Pronase. Young (6–8 d, *a*) and adult (2–4 months, *b*) C57BL/6 cells were treated with Pronase (2 mg ml⁻¹) (*Streptococcus griseus* protease) and DNase II (20 µg ml⁻¹) for 1 h at 37 °C in HBSS plus HEPES, washed five times and then cultured and assayed as in Fig. 1. Treatment with Pronase was either immediately after cell collection or after 24 h culture in Mishell-Dutton medium containing RAMG (200 µg ml⁻¹) and three washes. For comparison, re-expression after incubations of 1 and 24 h in Mishell-Dutton medium containing RAMG (200 µg per ml) are also shown. ○—○, 1 h RAMG; ○—○, 24 h RAMG; ●—●, 1 h Pronase; ●—●, 24 h RAMG, 1 h Pronase

independent⁶ B lymphocyte marker, the I region-associated antigens (Ia). As all panels of Fig. 3 show, the surface distribution of Ia was unaffected immediately after the clearance of sIg by RAMG in early and adult B lymphocytes. One day after incubation with RAMG, adult B lymphocytes still showed their Ia and had restored their sIg. In contrast, early B lymphocytes also retained their Ia but had restored their sIg poorly or not at all. We concluded, therefore, that these early B cells were still present in the culture and alive at this time but had failed to re-express their sIg. Two days after the end of a 24-h treatment with RAMG the situation seemed to be changing, however. The percentage of early Ia-positive cells was declining, implying that, as a result of the prolonged ligand-receptor interaction, the original early B lymphocytes were either dying or were changing other cellular characteristics.

In addition to surface markers, the functional property of lipopolysaccharide (LPS)-induced mitogenesis was also studied after receptor clearance. Table 1 shows that the LPS mitogenic response of adult B lymphocytes was affected minimally, if at all, after treatment with RAMG. In striking contrast, early B lymphocytes had a marked reduction in LPS-induced mitogenesis after the same procedures. Thus, the failure to re-express receptors after RAMG clearance was accompanied by the loss of responsiveness to the potent B cell mitogen LPS.

Although the mechanism of this receptor-mediated inactivation of early B lymphocytes is not clear, certain conclusions can be drawn.

First, the inactivation seems to be a direct consequence of the interaction of RAMG with sIg and does not involve suppressor-type T-cell effects. In this system the RAMG only interacts with B lymphocytes. Furthermore, in experiments involving mixtures of adult and young spleen cells, each population reacts independently, neither one influencing the other in any direction. Second, this inactivation was not associated with proliferation of B cells after treatment with RAMG. We have failed repeatedly to detect any mitogenic

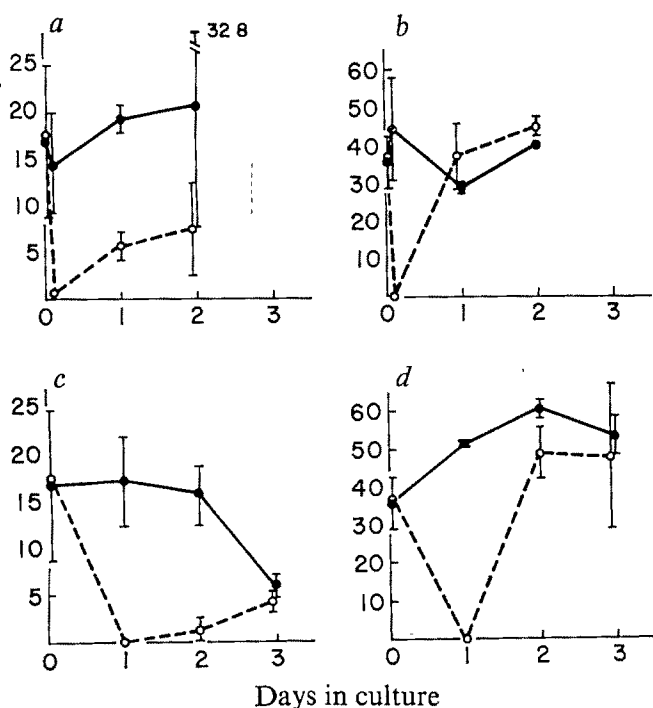

Fig. 3 Re-expression of surface Ig in relation to surface Ia. The four panels show young and adult AKR cells treated for 1 and 24 h with RAMG as in Fig. 1. For each assay point, a tube of cultured cells was washed once, pelleted, resuspended in 50 μ l rhodamine-conjugated RAMG (R-RAMG), (1.3 mg ml⁻¹), incubated for 30 min at 4 °C, washed three times, and resuspended in 20 μ l normal mouse serum. Twenty microlitres fluorescein-conjugated ATH anti-ATL spleen cell serum (F anti-Ia) were added, and the cells were incubated for 30 min at 4 °C, washed twice and resuspended to 10⁷ per ml. The cells were then scored for the presence of Ig (rhodamine stain) and Ia (fluorescein stain). *a*, Young cells, 1 h RAMG; *b*, adult cells, 1 h RAMG; *c*, young cells, 24 h RAMG; *d*, adult cells, 24 h RAMG. ●, % cells Ia (+) by FITC-a Ia; ○, % cells Ig (+) by R-RAMG.

effect of RAMG on early or adult murine B lymphocytes. Finally, this receptor-mediated inactivation seems to be controlled by some intracellular mechanism independent of the presence or absence of ligand-receptor complexes on the membrane. Ault *et al.*⁷ showed that after binding a highly tolerogenic polypeptide of *D*-amino acids, primed adult mouse spleen cells did not regain antigen-binding capability. Also, the complexes were not totally cleared from the cell surface. One could explain these results⁷ by postulating a relationship between clearance of complexes and expression of new receptors. This explanation does not apply to our experiments, however, since the early B cell does clear its surface of complexes. Also, even if some long lasting complexes were present, the Pronase should have removed them and released the cell.

These results show that the interaction of the antigen receptors of an early B lymphocyte with a specific ligand leads to the inactivation of two fundamental B cell processes—receptor re-expression and LPS-induced mitogenesis. This phenomenon may be the basis for several situations of immunological unresponsiveness. The inactivation reported here could explain, in part, the phenomenon of allotype suppression, as well as the analogous cases of suppression of specifically committed cells by anti-receptor antibody^{8,9} and of cells bearing a particular Ig class by class-specific antibody¹⁰. Further, young animals are notoriously easy to render specifically tolerant towards antigen. Although other cells and mechanisms are probably also operative¹¹, a specific antigen may directly turn off the early B lymphocytes by the process discussed here. Studies are in progress evaluating this point directly on antigen-binding lymphocytes. Finally, the inactivation of early type B lymphocytes could also have a role in adult tolerance. There is

evidence that adult mouse spleen⁴ and bone marrow¹² contain some B lymphocytes of the type constituting the young spleen. These may be precursors which constantly repopulate the pool of competent adult B lymphocytes¹³. It is possible that the state of unresponsiveness in the adult, although complex, could be prolonged by the ligand-induced inactivation described here, having as its target the early type of B cell found in bone marrow. In this respect, it has been shown that adult bone marrow lymphocytes are very easily rendered tolerant by antigen *in vitro*¹⁴.

In vitro* recognition of carcinogen-induced local denaturation sites in native DNA by S₁ endonuclease from *Aspergillus oryzae

It is known^{1–4} that the AAF-addition products obtained in the reaction of the ultimate carcinogen, N-acetoxy-N-2-acetylaminofluorene (AAAF) with DNA *in vitro* are essentially the same as those isolated from liver DNA of rats fed with N-2-acetylaminofluorene (AAF). Thus, the modifications of DNA secondary structure observed *in vitro* should reflect DNA alterations arising *in vivo*. It has been shown^{5–9} that the main alteration induced by the fluorene ring is the creation of locally disorganised regions inside the double-helical structure. We now show that S₁ endonuclease (EC3.1.4.) from *Aspergillus oryzae* is able to excise the local regions of denaturation induced in native DNA molecules by AAAF.

When the kinetics of the hydrolysis of a carcinogen-modified native DNA sample (DNA-AAF) by endonuclease were measured they were found to be intermediate between the kinetic curves of native and fully denatured DNA (Fig. 1a). Moreover, by following A₃₀₅, the acid-soluble material was shown to contain fluorene (Fig. 1b). Analogous measurements using native DNA modified by two derivatives of AAF are also reported.

The first, N-acetoxy-N-2-acetylaminofluorene (AAAF), is a model of the ultimate metabolite of the strong carcinogen, N-2-acetylaminofluorene (AAF)¹⁰. According to the general mechanism of activation of arylamides¹, the second, N-acetoxy-N-2-acetylaminofluorene (AAAF), may be a metabolite of the non-carcinogen N-2-acetylaminofluorene (AAIF)¹¹. A native DNA sample modified by the fluoro-derivative (DNA-AAAF) showed almost the same behaviour towards S₁ as DNA-AAF (Fig. 1a). On the other hand, hydrolytic attack on a DNA sample modified to the same extent with the iodo-derivative (DNA-AAIF) was much slower (Fig. 1). These results fit very well with those obtained previously using purely physicochemical experiments^{5–8}.

How the covalently linked fluorene residues induce local opening of the double helix may be viewed schematically as

Fig. 1 Kinetics of hydrolysis of different calf thymus DNA samples by S_1 endonuclease from *Aspergillus oryzae*. ∇ , Native DNA; \blacktriangledown , heat-denatured DNA; \circ , DNA-AAFF; \blacksquare , DNA-AAFF; \bullet , DNA-AAIF. DNA was prepared from calf thymus²³ and had the following characteristics: hypochromicity at 260 nm: 40%, $S_{20,w}$: 21S; ϵ_{260} : 6,420; protein content $\leq 0.8\%$ by weight. Denatured DNA was obtained by heating a DNA sample in a sealed vial to 100 °C for 10 min. To avoid DNA renaturation the sample was rapidly chilled in ice. Reaction of native DNA samples with the fluorene derivatives was carried out as described previously⁵. All fluorene-reacted DNA samples have approximately 5% of their bases modified. Hydrolysis experiments were carried out as described by Vogt in the following buffer: 0.03 M sodium acetate, pH 4.6, 0.05 M NaCl 1 mM $ZnSO_4$, 5% glycerol. DNA concentration was about 180 $\mu g\ ml^{-1}$. Enzyme was prepared according to Vogt²². According to the definition of one unit of nuclease activity²² our enzyme solution titrates at 18 U/10 μl . *a*, Concentrations of acid-soluble material were measured as follows: incubations, carried out at 45.0 ± 0.1 °C, were terminated by chilling and addition of 0.6 ml ice-cold 10% perchloric acid to 0.3 ml aliquots. Samples were centrifuged for 15 min at 5,000 r.p.m. and A_{260} determined. *b*, Percentage of acid-soluble fluorene was determined by recording A_{305} .

follows. The ultimate carcinogen (AAAF) reacts mainly at position C-8 on guanine residues^{12,13}. If polynucleotides are strictly held in a static double-helical structure, there is no possibility of chemical reaction at position C-8 of purines (and C-6 of pyrimidines). Thus, to enable a successful carcinogen attack, we must presume a dynamic state for native DNA¹⁴, with transiently open base pairs ('breathing units'), as proposed by von Hippel *et al.*¹⁵. A consequent conformational change brings the modified base from its *anti* conformation to a *syn* conformation by rotation around the glycosyl linkage¹⁶. The three-dimensional conformation, however, is not yet clear.

To explain the local denaturation sites induced by the fluorene ring indicated by the decrease in melting temperature^{5,14,17} and by the kinetics of formaldehyde unwinding^{6,7}, we have proposed an 'insertion-denaturation model' in which the fluorene ring is accommodated between the two nearest base plates⁵⁻⁸. This model has been confirmed by Weinstein *et al.*^{9,18}. Chan *et al.*¹⁹ measured the orientation of the fluorene in renatured DNA of T4 phage and found a value consistent with the AAF residue being constrained to lie along the helix-winding angle. I have, however, obtained measurements of electric dichroism showing the fluorene ring perpendicular to the helix axis in the case of DNA-AAFF and DNA-AAFF (R.P.P.F, unpublished). On the other hand, for the iodo-derivative we found the angle

between the transition moment of fluorene at 305 nm and the helix axis to be 60°.

We may distinguish therefore two different addition products: denaturing addition products (DNA-AAF and DNA-AAFF), in which the fluorene ring gives rise to single-stranded-like regions; these regions are S_1 -sensitive; non-denaturing addition products (DNA-AAIF), in which the insertion of the fluorene ring is probably hindered (in this case by the bulky iodine atom). As local helix opening does not occur, little or no hydrolysis by the S_1 nuclease is detected. Work on the chemical nature of the addition products in DNA-AAFF and DNA-AAIF is in progress.

I stress the increased importance in chemical carcinogenesis of the reaction of cells to limit damage to DNA. Cellular repair mechanisms are a consequence of the local distortion or breakage of DNA strands²¹. Enzymes able to recognise and to excise distorted regions of DNA are probably involved in the earliest step of cellular repair.

At present there is no evidence for a correlation between the presence of locally disorganised groups of nucleotides in native DNA and the carcinogenic process. There is, however, a striking correlation between carcinogenic power of aromatic amides and the 'molecular thickness' of their aromatic ring²⁰. In most cases, if the aromatic ring is either non-planar or substituted by a bulky atom or group, the corresponding amide shows little or no carcinogenic activity.

Although AAF was essentially inactive as a carcinogen, it does not necessarily follow that AAAIF is also non-carcinogenic. The parent compound may not be 'activated' (that is, N-hydroxylated and esterified) *in vivo*. Direct tests on the carcinogenicity of AAAIF are now in progress.

We thank Professor M. P. Daune for his constant interest, Professor P. Chambon for S_1 nuclease, and Professor J. Neelin for reading the manuscript.

Localisation of satellite DNA sequences in nuclei and chromosomes of two plants

MANY eukaryotic DNAs can be resolved into two or more components by centrifugation to equilibrium in neutral $CsCl^{1,2}$, the minor components being called satellite DNAs. In addition to $CsCl$ satellites, minor portions of the genome have been

resolved from the main DNA band by differential binding with Ag^+ or Hg^{2+} ions, followed by centrifugation in Cs_2SO_4 .

The satellite DNA in mouse, isolated as either a CsCl satellite or as a Ag^+ complex, has been localised, by *in situ* hybridisation, over the chromocentres in interphase nuclei, and at the centromeres of all the metaphase chromosomes^{3,4}. Further satellites have been investigated in various animal species including *Drosophila*^{5,6}, *Rhynchosciara*⁷, the higher apes and man⁸. The small size of the chromosomes in plants containing CsCl satellite DNA⁹ has frustrated attempts to localise these sequences cytologically. We describe here the properties of a $\text{Ag}^+/\text{Cs}_2\text{SO}_4$ satellite DNA from *Scilla sibirica*, a plant with large, morphologically distinguishable chromosomes containing heterochromatin¹⁰, and demonstrate by *in situ* hybridisation the nuclear and chromosomal location of these sequences. Some preliminary observations are presented for an $\text{Ag}^+/\text{Cs}_2\text{SO}_4$ satellite DNA isolated from *Vicia faba*.

The nuclear DNA of *S. sibirica* forms a slightly asymmetrical band with a buoyant density of 1.701 g cm^{-3} on centrifugation in CsCl (Fig. 1a). When the DNA is complexed with Ag^+ ions a light satellite, comprising 5–10% of the total DNA is completely resolved from the bulk of the DNA on centrifugation in Cs_2SO_4 (Fig. 1b). After purification of this band on preparative $\text{Ag}^+/\text{Cs}_2\text{SO}_4$ gradients the satellite DNA forms a single homogeneous band at 1.705 g cm^{-3} in CsCl (Fig. 1c). This $\text{Ag}^+/\text{Cs}_2\text{SO}_4$ satellite DNA probably accounts for the asymmetry of the total DNA band in Fig. 1a.

Figure 2a shows the thermal denaturation curve of *S. sibirica* satellite DNA in $0.25 \times \text{SSC}$ (0.04 M NaCl and $0.004 \text{ M Na-citrate}$, $\text{pH } 7.2$). The profile reveals at least three components of very different C+G composition, separable by thermal denaturation but apparently similar in buoyant density in CsCl . The major melting component (60%), with a T_m of 91.5°C in $0.25 \times \text{SSC}$, corresponds to a high C+G composition of about 75%. Figure 2b shows that the renaturation kinetics of the satellite in $0.25 \times \text{SSC}$ are at least biphasic. Estimation of the second order rate constant for the fast component, assuming that this contributes 60% of the total satellite DNA, gives a value of $780 \text{ mol}^{-1} \text{ s}^{-1}$ in $0.5 \times \text{SSC}$. This is very similar in

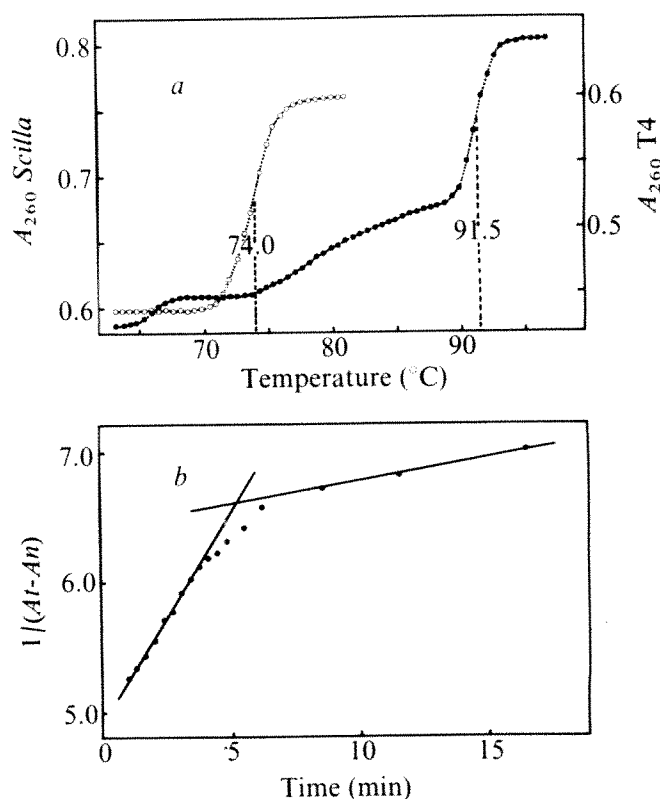

Fig. 2 a, Thermal denaturation of *S. sibirica* satellite DNA. Absorbance readings of T4 (○) and purified *S. sibirica* satellite DNA (●) in $0.25 \times \text{SSC}$ were taken at intervals in a Unicam SP 8000 spectrophotometer as the temperature control block was raised 1°C per 4 min. b, Renaturation of *S. sibirica* satellite DNA. Purified satellite DNA in $0.25 \times \text{SSC}$ was denatured at 100°C for 5 min, and then renatured at 70°C . The reciprocal of the remaining hyperchromicity ($1/(A_t - A_n)$, where $A_n = A_{260}$ of renatured DNA at time t) was plotted against time.

Fig. 1 Microdensitometer scans of ultraviolet photographs of total DNA from *Scilla sibirica*. DNA was prepared from young leaf tissue and analysed in a Model E analytical ultracentrifuge at 44,000 r.p.m. at 25°C for 20 h (ref. 19) a, $3 \mu\text{g}$ total DNA in $\text{CsCl} + 1 \mu\text{g}$ *Micrococcus lysodeikticus* marker DNA (1.731 g cm^{-3}); b, $20 \mu\text{g}$ of total DNA in Cs_2SO_4 with 0.3 M ratio of Ag^+ to DNA phosphate, $\text{pH } 8.0$; c, $3 \mu\text{g}$ of pure satellite DNA from the $\text{Ag}^+/\text{Cs}_2\text{SO}_4$ gradient $+ 1 \mu\text{g}$ of *M. lysodeikticus* DNA in CsCl .

complexity to mouse satellite DNA and the fast component of melon satellite DNA¹¹.

Figure 3a–e shows photomicrographs of autoradiographs of cytological preparations made after hybridisation with complementary RNA (cRNA) transcribed *in vitro* from pure satellite DNA of *S. sibirica*. The grains are clearly localised at interphase (Fig. 3a) over the conspicuous chromocentres characteristic of the species^{10,12}. The label is 24 times more concentrated over the heterochromatin than the euchromatin, a factor which is not accounted for by the different density of DNA in heterochromatin, which is only 2.5–3 times^{13,14} more concentrated than the euchromatin. At metaphase (Fig. 3b–d) clusters of grains appear over restricted regions of the chromosomes. The longest homologous pair (1, Fig. 4b) and one of the shorter pairs (5) have grains restricted to the end of one arm. Another pair (2) is similar but in four of 18 such chromosomes examined grains were localised at both ends. The third pair contained relatively few grains, with localisation occurring in only four of 18 chromosomes examined. The fourth pair showed clear distal and interstitial grain clusters and the sixth showed localisation either at one end of the short arm or interstitially on the long arm, with about equal incidence. This may be explained by heterochromatic (H) segment heterozygosity¹⁵ or chromosome inversion. This distribution of satellite DNA corresponds closely with the H segments as revealed by cold treatment¹² (Fig. 4a). These H segments are stained by Geimsa¹⁶, and appear as bands of low fluorescence after treatment with quinacrine mustard or quinacrine¹⁷.

There are usually about twice as many grain clusters and H segments in the metaphase chromosomes as in the interphase

Fig. 3 *In situ* hybridisation of *S. sibirica* and *V. faba* satellite DNAs. RNA complementary to pure satellite DNA was transcribed *in vitro* using all four ^3H -nucleoside triphosphates²⁰. Colchicine-treated roots were fixed in 3:1 ethanol-acetic acid for 1 h at room temperature followed by further treatment with 45% acetic acid for 24 h. The root tips were squashed on to slides, the coverslips removed, and the preparations denatured in $0.1 \times \text{SSC}$ at 100°C for 0.5 min. After dehydration and air drying, the slides were hybridised with cRNA (specific activity 10^8 d.p.m. μg^{-1} , $2 \mu\text{g cm}^{-2}$) for 5.5 h at 75°C in $6 \times \text{SSC}$. The slides were washed in $2 \times \text{SSC}$, treated with RNase and extensively washed in $2 \times \text{SSC}$. After dehydration and drying the slides were coated with Ilford K2 photographic emulsion and exposed in a light-proof, desiccated box at 4°C for 5 weeks. The preparations were developed in Kodak D19b developer, fixed and washed before staining with Geimsa (pH 6.9) and mounting in Euparal. *a*, Interphase nucleus of *S. sibirica* showing localised labelling of the chromocentres. *b, c, d*, Metaphase cells of *S. sibirica* ($2n = 12$) showing mainly distal localisation of the hybridised cRNA. *e*, Prophase of *S. sibirica*. *f*, Interphase nuclei of *V. faba*. *g, h*, Individual chromosomes of *V. faba*. The bars represent $10 \mu\text{m}$.

or prophase nuclei, (Fig. 3e), suggesting a link between repeated satellite sequences and somatic chromosome association and mechanics¹⁸.

In situ hybridisation of an $\text{Ag}^+/\text{Cs}_2\text{SO}_4$ satellite DNA from *Vicia faba* is also shown in Fig. 3f-h. In this instance the satellite sequences appear to be more generally spread over the nuclei (Fig. 3f), and over the chromosomes (Fig. 3g,h). There is a suggestion that the ends of the chromosome arms are unlabelled and, in addition, certain proximal regions. It is interesting that, in contrast to *S. sibirica*, most of the *V. faba* chromosome shows low fluorescence after quinacrine treatment¹⁷, suggesting a possible correlation with the satellite DNA sequences.

We conclude that the satellite DNA of *S. sibirica* is highly localised at positions which closely correspond to those of the cold sensitive heterochromatin. Although this heterochromatin

Fig. 4 Idiograms of *S. sibirica* ($2n = 12$). *a*, The position of the heterochromatic (H) segments revealed by cold treatment at -12°C is indicated by open segments (after Baumann¹²). *b*, Summary of nine analyses of complete metaphase cells of *S. sibirica*, after *in situ* hybridisation, showing the positions of the grain clusters. Grain clusters always present (●), sometimes present (○). Chromosome 6 was present in our material in either of the alternative forms shown.

is in some ways different from the centromeric form observed in other species such as mouse, it also contains highly repeated satellite DNA sequences.

Generation of discrete yeast DNA fragments by endonuclease RI

FINE structure genetic analysis has shown that the *ilv1* gene of yeast, *Saccharomyces cerevisiae*, is multifunctional¹⁻³. The *ilv1* gene product, threonine deaminase, shows catalytic activity, as well as participating in multivalent repression of other enzymes involved in isoleucine-valine biosynthetic pathways¹⁻³. A better understanding of the regulatory role of the *ilv1* gene product and other proteins, such as isoleucyl-tRNA synthetase, which in addition to the *ilv1* gene product seems to regulate *ilv2* and *ilv3* gene expression, could be obtained if a pure preparation of the various *ilv* genes were isolated in large quantities. One way of isolating the genes would be to use restriction enzymes to cleave yeast DNA which contains normal *ilv* genes and join the fragments to a bacterial plasmid. Because of the similarity of the isoleucine-valine pathways in yeast and *Escherichia coli*, the fused DNA could then be transformed into a strain of *E. coli* with a deletion in the particular *ilv* gene. Restriction enzyme-cleaved DNA from various sources has been amplified by growth in *E. coli*⁴⁻⁷. We have found that restriction enzyme *EcoRI* treatment of yeast DNA results in not only a reduction in the size of total DNA but also the generation of several distinct species of homogeneous size DNAs some of which are derived from ribosomal genes and others from mitochondrial genes.

DNA isolated from *S. cerevisiae* MAR-33 (ref. 8), although heterogeneous, was as large as 20×10^6 – 30×10^6 daltons. It migrates parallel to DNA of phage T3 and λ (molecular weight 23×10^6 and 31×10^6 , respectively) in 1% agarose. After treatment with *EcoRI* the yeast DNA profile was reduced in size but showed discrete bands. As Fig. 1 shows, at least ten distinct bands could be identified in a complete *EcoRI* digest of yeast DNA. Of these, the first and the last band was also present in untreated DNA. Thus, *EcoRI* treatment generated at least eight groups of homogeneously sized DNA fragments. More bands appeared in conditions of limited *EcoRI* digestion (Fig. 2). These seemed to be precursor, heavier DNA fragments that are found when *EcoRI* concentration is limiting (Fig. 2a) or the

Fig. 1 *EcoRI*-yeast DNA fragments appearing as discrete bands. 100 μ g of yeast DNA was treated with 5 μ l of the restriction enzyme *EcoRI* for various intervals at 37 °C. Above is an electrophoresis pattern of 10 μ g of *EcoRI* DNA (3 h incubation with *EcoRI*) in 1% agarose gel containing 0.5 μ g ml⁻¹ of ethidium bromide and run at 4 mA per gel for 2.5 h at 24 °C. The negative photograph of the gel was run through a scanner and is presented below the picture of the gel.

digestion is carried out for a short interval, such as 2 min (Fig. 2b). These intermediates disappeared in about 6 min at 37 °C when *EcoRI* was not limiting.

The ten major bands were next compared with the sizes of *EcoRI*-cleaved fragments of phage λ DNA (Fig. 3). The designated molecular weights of these fragments—13.7, 4.7, 3.7, 3.5, 3.0 and 2.1×10^6 —show that all eight *EcoRI*-cleaved yeast DNA fragments are below 2×10^6 (Table 1). When the proportion of these DNA fragments was calculated from the areas under the peaks of the gel scan in Fig. 1 the minimum number of DNA copies in each band could be estimated (Table 1). The two DNA bands present in the untreated yeast DNA gave the two extreme values. While the heaviest band, 4.1×10^6 daltons, was present in at least 10 copies, the smallest band, 1.6×10^6 daltons, was present in at least 1,900 copies. Three *EcoRI*-cleaved yeast DNA bands were present in at least 100 copies (1.0×10^6 – 1.6×10^6

Fig. 2 Heavier intermediate bands generated by *EcoRI* treatment on yeast DNA. *a*, The experiments were performed as reported in the legend to Fig. 1 with 15 μ g of yeast DNA and various concentrations of *EcoRI*. Nearly 8 μ g of this DNA was run on a 0.6% agarose gel at 4 mA per gel for 2.5 h. *b*, The experimental condition is that described in legend to Fig. 1.

† These two bands are present before *EcoRI* treatment.

‡ Estimated from known molecular weights of λ DNA fragments in Fig. 3.

§ Obtained by measuring areas under peaks of the gel seen in Fig. 1.

¶ Calculated from a value of 1.25×10^{10} daltons for haploid yeast DNA.

daltons) and four in at least 325 copies (2×10^5 – 4×10^5 daltons). All ten bands combined constituted at least 10% of the total yeast DNA. Thus, the bulk of the *EcoRI*-cleaved yeast DNA was non-repetitive and heterogeneous in size.

Although the discrete bands of *EcoRI*-cleaved yeast DNA indicate that fragments of specific size were generated, they do not indicate whether they were of homologous sequence. There are nearly 140 copies of DNA for ribosomal RNA and 320–400 copies of DNA for transfer RNA in a haploid yeast¹⁰. Both 18S and 26S ribosomal RNA arise from a common precursor RNA molecule of 2.5×10^6 daltons (refs 11 and 12) which constitutes

Fig. 3 Size relation of *EcoRI*-yeast DNA to *EcoRI*-phage λ DNA. 10 μ g of bacteriophage λ DNA and 20 μ g of yeast DNA were digested repeatedly with *EcoRI*. 2 to 4 μ g of these *EcoRI* treated DNA individually and combined were run in a 1% agarose gel at 0.6 mA per gel for 17 h in the absence of ethidium bromide. The gels were soaked for 30 min with 5 μ g ml⁻¹ of ethidium bromide before photography.

a total ribosomal DNA of 400×10^6 – 700×10^6 daltons (ref. 13). Most of the 400×10^6 – 450×10^6 daltons of chromosome I codes for nearly 70% of the total ribosomal RNA^{14–16}. Bands 2, 3 and 4 of *EcoRI*-cleaved yeast DNA also constitute a total molecular weight of 420×10^6 daltons (Table 1). But then each of the 17–20 yeast chromosomal DNAs is of this molecular size—between 400×10^6 and 600×10^6 daltons (refs 13 and 17).

To determine which of the ten bands contained ribosomal DNA, 18S and 26S ribosomal RNA were purified from isolated ribosomal subunits and hybridised¹⁵ with DNA extracted from four segments of the complete gel and then from each of the *EcoRI*-generated bands. As Table 2a shows, the bulk of the hybridisation occurred in that segment of the gel which consisted of bands 2, 3 and 4 (Fig. 1). DNA isolated from bands 2 and 4 predominantly hybridised with 18S rRNA whereas the hybridisation with 26S rRNA was restricted to band 2 (Table 2b). Thus band 4 contains 18S rDNA. The hybridisation with band 2 indicates that this band either contains both 18S and 26S rDNAs or that the 18S RNA preparation contains some 26S RNA. In any event, a minimal assignment of 26S rDNA to DNA fragments in band number 2 and of 18S rDNA to band number 4 is possible.

Table 2 Hybridisation of yeast ribosomal RNA with *EcoRI*-generated yeast DNA fragments

8 & 9	197	130

³H-ribosomal RNA (specific activity 0.3×10^6 c.p.m. μ g⁻¹) was isolated from yeast cells grown in the presence of ³H-adenine. The 60S and 40S ribosomal subunits were separated and the two RNA species were prepared by sedimentation through SDS-sucrose gradients. DNA fragments were eluted from various portions of the gel shown in Fig. 1 and immobilised on nitrocellulose filters. Low temperature hybridisation in the presence of formamide was carried out on these DNA-loaded filters with either 18S (4 μ g ml⁻¹) or 26S (4.5 μ g ml⁻¹) rRNA by a method very similar to that of Finkelstein *et al.*¹⁵. Nonspecific binding of ³H-rRNA to blank filters gave a value of 15 c.p.m. above background and has been subtracted from the above values. The values reported are the averages of duplicates.

The contribution of mitochondrial DNA in generating these fragments could be quite significant. Analytical ultracentrifugation has shown that the yeast DNA preparation contains between 5 and 6% of mitochondrial DNA. This alone would not account for all the yeast DNA bands. Furthermore, yeast DNA preparations isolated after isopycnic centrifugation in CsCl showed similar bands after treatment with *EcoRI* all throughout the gradient profile. This suggests that the bands are not exclusively of mitochondrial DNA (light density)¹⁸ or ribosomal DNA (heavy density)^{18–20} in origin. Bands 6 to 9 could be mitochondrial, however, since they are absent when yeast nuclear DNA separated from mitochondrial DNA by CsCl equilibrium centrifugation is subjected to *EcoRI* digestion and applied to the 1% agarose gel.

In conclusion, most yeast DNA fragments generated by *EcoRI* treatment are not highly repetitive, although several classes of homogeneously sized DNA species are found. Some of the

enriched DNA species seem to be mitochondrial while two size classes contain ribosomal DNA sequences. The easy availability of DNA sequences such as those for the ribosomal genes should enhance the development of the methodology for the isolation of the *ilv* structural genes.

We thank Dr Hiroaki Shizuya for the λ DNA and Dr David Finkelstein for advice on hybridisation experiments. K. N. is a postdoctoral fellow supported by a Moss Fellowship and the American Cancer Society. This research was supported by grants from the American Cancer Society, Moss Heart Center, Texas Heart Society and the U.S. National Science Foundation.

Determination of 5'-triphosphate terminus of 16S ribosomal RNA precursor

THE genes for the 23S and 16S rRNAs are physically linked¹. Using the drugs rifampicin and actinomycin D, it has been shown that the 23S and 16S rRNA cistrons are co-transcribed and the promoter is proximal to 16S rRNA cistron^{2,3}. Recent work with an *Escherichia coli* strain deficient in RNase III has provided further evidence for co-transcription, showing the presence of a long polycistronic RNA which could be cleaved to the immediate precursors of 23S and 16S rRNAs when treated with RNase III *in vitro*⁴. We have now studied the transcription of rRNA in *E. coli* using γ -³²P-labelled triphosphates and have shown that the 16S rRNA precursor in our preparation has a 5'-pppA end and that in our system it is neither cleaved nor replaced by 5'-pA as observed by Takanami⁵. We have not found any detectable 5'- γ -³²P-triphosphate end in the 23S rRNA species. This observation further verifies directly that both the 16S and 23S rRNAs belong to one transcriptional unit in the following order: promoter–16S–23S.

RNA transcription proceeds in the 5'→3' direction and the first nucleotide at the 5' end has so far been found to be a purine⁶, either ATP or GTP. We used γ -³²P-ATP and γ -³²P-GTP to study the initiation of rRNA transcription in *E. coli* spheroplasts. The presence of radioactivity in the nucleotide triphosphates of the RNA hydrolysate would represent incorporation of the label at the 5' end of the RNA. The advantage of using *E. coli* spheroplasts is that there is insignificant

Fig. 1 *E. coli* CP78 (*his*⁻, *leu*⁻, *thr*⁻, *arg*⁻, *thi*⁻, *rel*⁺) was grown in 20 ml minimal M9 medium until absorbance reached 0.1 (2×10^8 cells ml⁻¹). The culture was then spun down at 6,000 r.p.m. for 10 min at room temperature. The pellet was resuspended and shaken in 20 ml of a plasmolysing buffer containing 10⁻³ M EDTA, 0.12 M Tris, pH 7.8 for 3 min. This rendered the cells permeable to nucleotide triphosphates for no less than 15 min. The cells were then poured into 20 ml pre-warmed M9 minimal medium containing 0.5 mCi γ -³²P-ATP or 0.5 mCi γ -³²P-GTP (New England Nuclear, specific activity containing less than 0.1% of α -³²P-ATP and α -³²P-GTP as well as orthophosphate. γ -³²P-GTP has a specific activity of 0.0552 mCi mol⁻¹ and γ -³²P-ATP of 0.0316 mCi mol⁻¹). This labelling procedure was terminated after 15 min by pouring the culture into 5 ml frozen M9 buffer, and immediately spun down at 4 °C. RNA extraction was then carried out by resuspending the pellet in 25% sucrose, 0.01 M Tris, pH 7.2, and then following the hot phenol technique described in ref. 8. The RNA extract was precipitated by adding 0.1 ml ml⁻¹ of 3 M sodium acetate, and 2 volumes of cold ethanol, and left overnight at -20 °C. The precipitate was spun at 10,000 r.p.m. for 20 min, and resuspended in 1 ml of 0.01 M sodium acetate buffer, pH 5.1. The RNA (total) was analysed through a 5 cm, 1.2% polyacrylamide-agarose gel, and electrophoresed at 5 mA and 50 V for 1.75 h. The gels were sliced and exposed to X-ray sensitive films and developed.

background due to pyrophosphate exchange and little breakdown of triphosphates to monophosphates. Thus incorporation of nucleotides with phosphate labelled at the α -position is negligible.

In this system, the transcription is qualitatively normal, as evidenced by our separate studies on ³H-UTP uptake and titrations of *lac* or *gal* mRNA. The rate of RNA synthesis is, however, reduced to 30%. This was also observed by others⁷. The nucleases responsible for processing the 16S and 23S precursors in this system become very inefficient, as shown in autoradiograms of RNA isolated from spheroplasts and subjected to polyacrylamide gel electrophoresis (Fig. 1). As Fig. 1 shows, the autoradiogram of the normal rRNAs in *E. coli* has four bands. From top to bottom of the gel they are the precursor 23S (p23S), matured 23S m23S, precursor 16S (p16S) and mature 16S (m16S) RNA. As for the rRNAs from the *E. coli* spheroplasts only the 23S and 16S precursors are seen.

RNAs labelled with γ -³²P-nucleotide triphosphate were isolated from *E. coli* spheroplasts. They were fractionated into p23S and p16S by sucrose gradient and digested by alkali treatment (see footnote of Table 1). The hydrolysates from p23 and p16 were then spotted on thin-layer chromatographic sheets

Table 1 Radioactivity from the alkaline hydrolysates of rRNAs isolated from *E. coli* CP78 spheroplast

³² P-labelled purine nucleotides	Radioactivity (c.p.m.) obtained from TLC spots with rRNA samples*	
	p16S†	p23S†
³² pppAp	367	0
³² pppGp	0	0
AMP ³²	187	386
GMP ³²	146	337

* γ -³²P-labelled ATP or GTP was used to label RNA isolated from *E. coli* CP78 spheroplasts. The RNA extract (for method see legend under Fig. 1) was subjected to a linear 5–20% sucrose gradient centrifugation at pH 5.1, using SW 40 rotor and Beckman ultracentrifuge L5-40 at 4 °C and centrifuging for 12 h at 25,000 r.p.m. The fractions containing p23S and p16S RNAs were collected and their specific activities determined by A_{260} (410 and 487 c.p.m. μg^{-1} , respectively). These two species of rRNA were first dialysed in distilled water for 6 h to eliminate sucrose, and then hydrolysed separately by treating with 0.3 M KOH at 37 °C for 16 h. The hydrolysate contains nucleotide tetraphosphates and monophosphate⁶. The hydrolysates were then neutralised by adding appropriate volumes of 1 M perchloric acid. The precipitate, potassium perchlorate, was pelleted by centrifugation at 12,000 r.p.m. for 20 min in a Sorvall RC2B centrifuge at 4 °C. Fractions of the supernatant (600 c.p.m. each or approximately 1.5 μg) were spotted on and analysed by thin-layer chromatography using plastic backed sheet obtained from Macherey-Nagel, Polygram cel 300 PEI. Non-radioactive ATP AMP, GTP and GMP were also spotted on the same sheet as reference markers. The chromatographic sheet was run in 1 M LiCl, 1 M acetic acid for 2.5 h at 4 °C. The various spots could be identified by exposing the sheet under a mineral ultraviolet lamp. The tetraphosphates and monophosphates spots were cut out carefully, dried at room temperature for 2 h and then counted on a Packard scintillation counter (Model 3375, Tri-Carb) in toluene-based Omnifluor.

†p16S and p23S refer to precursors of 16S and 23S rRNA species.

and separated. The results are tabulated in Table 1. There is a conspicuous tetraphosphate spot for p16S RNA hydrolysate that is not detectable in the case of p23S rRNA hydrolysate. Therefore, for the p23S rRNA hydrolysate, the region corresponding to the tetraphosphate spot was located by adjusting with the 16S rRNA spot by eye estimation, and a considerable area of the TLC around the region was cut. Lines 1 and 3 of column 4 (Table 1) represent the radioactivity (c.p.m.) of the tetraphosphate spots for p16S (precursor of 16S rRNA) and p23S (precursor of 23S rRNA) rRNA hydrolysates, which are 367 c.p.m. and 0 c.p.m. respectively. The first and third line in Table 1, column 5 are the radioactivity due to XM³²P spots of p16S and p23S hydrolysates.

Table 1 indicates that there is a breakdown of the γ -³²P-triphosphate label, but the extent is not very high. Considering the specific activity of γ -³²P-ATP (2.5 $\mu\text{Ci ml}^{-1}$) used for labelling rRNAs and the fact that only one 5'-³²P-labelled ATP would appear on the 5' end of each p16S RNA molecule the amount of ³²P-monophosphate, incorporated along the length of p16S or p23S rRNA is calculated as less than 0.0001% of input radioactivity. Incorporation of the labelled phosphorus into the entire length of the rRNA molecules is presumably the reason for the presence of approximately double the number of c.p.m. in the monophosphate spots of p23S compared with that of p16S RNA. γ -³²P-nucleotide triphosphates were incorporated into the p16S rRNA but not into the p23S rRNA. Because the first nucleotide incorporated always retains its triphosphate ends, we can minimise the possibility of pyrophosphate exchange into the triphosphate position. Therefore any radioactivity present in the tetraphosphate spots would be the γ -labelled ³²P-nucleotide triphosphates.

To verify which of the two purines (γ -³²P-ATP or γ -³²P-GTP) was incorporated as the first nucleotide, similar experimental procedures were repeated using only γ -³²P-GTP. Results are tabulated in Table 1, lines 2 and 4. Tetraphosphate spots of both p16S and p23S RNA hydrolysates contained no detectable radioactivity. This suggests that GTP was not the

initiating nucleotide triphosphate and therefore ATP must be the first nucleotide incorporated.

We therefore conclude, since the p16S rRNA hydrolysate contained ³²P-radioactivity in its tetraphosphate spot and p23S rRNA did not, that: (1) initiation of rRNA transcription can only take place in the 16S rRNA gene, (2) ATP is the initiating nucleotide, and (3) transcription initiating at 16S rRNA proceeds towards 23S rRNA without further reinitiation.

We thank Dr J. F. T. Wong for advice and for reading the manuscript. This work was supported by the National Research Council of Canada.

Corrigenda

In the article "Collimation of auroral particles of time-varying acceleration" by D. S. Hall and D. A. Bryant (*Nature*, **251**, 402; 1974) there is an error in equation (10). The denominator should read $\sqrt{2(\sigma/E_0)}$ and not as printed. Also the value of A in the legend to Fig. 1 should read $9.1 \times 10^8 \text{ cm}^{-2} \text{ s}^{-1} \text{ sr}^{-1} \text{ keV}^{-1}$ and not as printed.

In the article "Oxidation of nickel by nitric oxide as a new strong oxidant" by Y. Takasu, Y. Matsuda, S.-I. Maru and N. Hayashi (*Nature*, **255**, 544; 1975) there are several errors in the figures and legends. On the ordinate of Figs 2 and 3, for K_1 read K_1' . The legends to Figs 2 and 3 should read:

Fig. 2 Relationship between K_1' ($\text{g cm}^{-2} \text{ s}^{-1}$) and temperature ($P_{\text{NO}} = 10 \text{ mmHg}$). $E = 17.8 \text{ kcalorie}$.

Fig. 3 Relationship between K_1' ($\text{g cm}^{-2} \text{ s}^{-1}$) and the pressure of nitric oxide (700 °C). $n = 0.74$.

Errata

In the article "Excision of thymine dimers from specifically incised DNA by extracts of xeroderma pigmentosum cells" by K. Cook, E. C. Friedberg and J. E. Cleaver (*Nature*, **256**, 235; 1975) the following corrections should be made. In line 3 of the legend to Table 1, for 50–100 erg mm^{-2} read 5–10 J m^{-2} . The list of authors should include as the last author H. Slor, Department of Human Genetics, University of Tel Aviv, Israel. The asterisk after J. E. Cleaver should indicate that his address is the Laboratory of Radiobiology, University of California School of Medicine, San Francisco, California.

In the article "Pathogenicity and cerato-ulmin production in *Ceratomyces ulmi*" by S. Takai (*Nature*, **252**, 124; 1974) there is an error in the second sentence of paragraph 6. For (120 mg ml^{-1}) read (120 $\mu\text{g ml}^{-1}$).

matters arising

Formaldehyde polymers in interstellar space

THE suggestion¹ that polyoxymethylene (POM) crystals exist in interstellar space must be reviewed in terms of the thermodynamics of polymer-monomer equilibria². The formaldehyde-POM equilibrium is notoriously mobile³, unless the polymer is end-capped⁴. This treatment is applied to commercial samples such as those whose infrared spectra were reported by Tadokoro *et al.*⁵, which provided data for the argument¹ for POM in space.

The partial pressure of formaldehyde in equilibrium with POM has been determined over a small temperature range⁶, and, by extrapolation, the partial pressure at 20 K (the temperature at which the polymer is supposed to form¹) is equivalent to $2 \times 10^{-14.3}$ molecules cm^{-3} . Chemical thermodynamics thus supports the hypothesis that the polymer exists in some regions of space: a mechanism for initiating the polymerisation process on the surface of mineral particles may be provided by ionising radiation, though the rate of propagation must be extremely small at such a temperature.

At 445 K, the temperature assumed for the dust in the Trapezium nebula¹, the equilibrium partial pressure of formaldehyde above POM, is more than 1 atmosphere, which is greatly in excess of any likely nebulous condition. Only if there were a means for end-capping interstellar POM would it exist at 445 K, and the survival time of such material in the ionising radiation of an H II region would be short. It is, therefore, doubtful that the infrared emission from the Trapezium nebula is from a POM source at that temperature.

It is interesting to note that the concentration of formaldehyde molecules in the Trapezium nebula seems to be greater where ionised atomic material is most dense⁷, and it is possible to postulate a role for the formaldehyde-POM equilibrium in the globular model⁸ of the core of the nebula, assuming that the temperature and formaldehyde molecule concentrations were suitable.

WICKRAMASINGHE AND SANTHANAN REPLY—Preliminary remarks on the end-capping of formaldehyde polymers have already been made in the context of the formation of interstellar POM¹. The vapour pressure data for such stabilised polymers (for example, resins consisting mainly of $(\text{H}_2\text{CO})_n$) do not seem to be readily available. The extrapolations of vapour pressure^{2,3} data discussed by Fawcett⁴ relate to unstabilised POM. For a gas kinetic temperature of 100 K, as may be appropriate to an H I region, the number density of gaseous H_2CO molecules in equilibrium with unstabilised POM reaches the observed value $\sim 10^{-8} \text{ cm}^{-3}$ at a particle temperature, T , $\sim 115 \text{ K}$. As that temperature is less than the temperature of most grains, there can be no doubt about the stability of POM even if it were not suitably end-capped in normal interstellar conditions.

We consider it unlikely, however, that interstellar polyformaldehyde will not be end-capped. The formation of POM mantles or whiskers is expected to occur mainly in molecular clouds in the presence of considerable abundances of OH, H_2O and other molecules including CH_3OH . The H_2CO polymerisation could be initiated by the well established process of anionic polymerisation⁵. For example, HO^- from interstellar water molecules may have a crucial role:

End-capping which would ensure maximum stability may be achieved by a similar interaction with interstellar methanol (CH_3OH) molecules.

The polymerisation of interstellar formaldehyde could be initiated and

end-capped by this or any other process involving anionic attack. Suitably end-capped formaldehyde polymers (for example, CH_2O resins) are highly stable at room temperature. Such crystalline polymers are expected to have sufficiently low vapour pressures to ensure their stability in H II regions up to temperatures, T , of about 400–500 K, or even higher. Particles heated to temperatures T , of more than 300 K could account for the observed 8–12 band in the Trapezium nebula^{5,6}.

Longitudinal photons in the fireball

BYRNE AND BURMAN have discussed the significance of astrophysical data for the problem of the photon mass¹. A question might arise concerning the possible presence of longitudinal photons in the microwave background were the photon mass not zero. In true thermal equilibrium, the longitudinal modes of the field would have to be populated to the same extent as the transverse modes. Bass and Schrödinger concluded some time ago that millions of years would be required for an appreciable fraction of longitudinal photons to build up in any terrestrial situation². Such time intervals, however, are available when dealing with cosmology.

The probabilities for the emission of longitudinal and transverse vector mesons with wave number k in a given process are in the ratio $m^2 c^2 / (\hbar^2 k^2 + m^2 c^2)$, where m is the meson rest mass³. When $\hbar k \gg mc$, this is approximately $(\lambda/\lambda_c)^2$, where λ is the wavelength and $\lambda_c = h/mc$. If the mean free path of the photon is L , the number of collisions per second is c/L , and the fraction of transverse photons converted

into longitudinal photons every second will be $(c/L)(\lambda/\lambda_c)^2 \equiv 1/\tau$. Also $1/L \approx n\sigma$, where n is the density of scatterers and σ the scattering cross section. We are concerned with the photons of the fireball moving through hydrogen, and can assume σ to be the cross section for Rayleigh scattering: $\sigma \approx a^2\lambda_b^4/\lambda^4$, where a is the classical electron radius and λ_b is the wavelength corresponding to the binding energy for hydrogen, about 10^{-5} cm. Both λ and n will change because of the expansion of the Universe: $\lambda = S\lambda_0$ and $n = n_0/S^3$, where λ_0 and n_0 are the quantities at epoch t_0 and S is the cosmological scale factor, chosen so that $S_0 = 1$. That gives:

$$\tau \approx S^5 \lambda_0^2 \lambda_c^2 / cn_0 a^2 \lambda_b^4$$

The factor τ depends strongly on S , which is now of the order of 1,000 if the initial epoch is that of the decoupling of the fireball radiation and matter; it is smallest when $S = 1$, $n_0 \approx 10^4$ atom cm^{-3} and $\lambda_0 \approx 10^{-4}$ cm. If $m = 10^{-52}$ g (ref. 4) then $\tau \approx 10^{44}$ yr. Thus, the fraction of longitudinal photons in the field after even many times 10^{10} yr is negligible. Even though long times are available, the free paths of photons are too long for sufficient scattering events to occur.

Do epicentres migrate on the San Andreas Fault?

WOOD AND ALLEN¹ have suggested that seismicity on a portion of the San Andreas Fault can be used in support of a model of recurring migration of epicentres. They considered 27 earthquakes of magnitude, $M \geq 5$ within 30 km of the fault between 35.5°N and 38.5°N which occurred between 1930 and 1972. Five parallel line segments are drawn through the time-latitude plot of 27 points; the common slope of the lines is presumed to give the velocity of migration of earthquakes. Several of these events correlate with one another; any line in the neighbourhood of events that are close together in latitude and time will provide a satisfactory fit.

Obvious clustered events are the quadruplet (1,2,3,4) and the pairs (15,16; 5,6; 19,20; and 25,26) (Table 1 of Wood and Allen). Probably, other correlated events could be found were a different model used. Further, event 13 seems not to have been used in the fit.

Thus, there are 19 or fewer independent events in the data set. If a model is used in which the slopes of the line segments are fixed, then there are 19 or fewer degrees of freedom in the data, which are used to fit the intercepts of the segments.

The number of degrees of freedom in the model used by Wood and Allen may be about 15 in addition to the common slope: that is, the intercepts and end points of each of the five lines. The number of degrees of freedom in the end points is a function of the length of the segments and is difficult to evaluate. Thus, the number of degrees of freedom in the model is roughly equal to the number of degrees of freedom in the data, and we conclude that there are inadequate data to support the parametric complexity of the migration model. We believe that the apparent migration of epicentres along part of the San Andreas Fault is an artefact of Wood and Allen's model.

Wood and Allen forecast an earthquake with $M \geq 5$ in a restricted time-space interval along the San Andreas Fault. Though the complexity of the model makes it easy to give qualitative predictions, quantitative predictions in terms of probabilities remain difficult. Wood and Allen have avoided the question of estimating the risk that is: the probable number of shocks that will occur in the time-space region identified as dangerous. We can calculate the risk on the basis of a simpler model involving a considerably smaller number of degrees of freedom. Suppose that earthquakes are Poissonian between 36.75° and 37.05°N . Seven earthquakes are then found in the $25 \text{ yr} \times 33 \text{ km}$ time-space region; the area identified as dangerous by Wood and Allen is about $6 \text{ yr} \times 17 \text{ km}$. Thus, 0.86 ± 0.31 shocks can be expected in the defined time-space interval. Dropping the constraint that the earthquake catalogue has a space-time envelope, and assuming instead that shocks occurred randomly between 1930 and 1972, then 0.50 ± 0.19 shocks with magnitudes of more than five will occur in the smaller time-space interval.

Competition and species abundance

HEBERT *et al.*¹ used samples of the aerial population of Macrolepidoptera, collected at light in Ontario, Canada, to advance an argument in competitive population dynamics. Although not entirely explicit, it seems to run as follows. Given the "generally conceded" initial premise that interspecific competition is greatest between closely related sympatric species, the hypothesis that species abundance is controlled by level of competition can be tested by the relationship between mean species' population density and their taxonomic distance. In other words, in a sample from a multispecies population, the mean number of individuals per species in each family (N_s) is expected to be negatively correlated with the number of species in that family (S_f); making the provisional assumption that the relationship is causal.

The general conclusion reached by Hebert *et al.*¹ from their evidence of an inverse relation between family size and the abundance of species, was as expected; "family differences . . . are due to competitive interactions." The experiment raises questions at all levels, technical, analytical, interpretative and logical and, because the issue is a central one, we will take these up in more detail elsewhere. Our present purpose is to show that results like these are not invariably obtained from samples of this kind and, therefore, the conclusion as stated is not general.

The data in Table 1 are sums of seven replicate samples, each one a single year's

Table 1 Species abundance and mean no. of individuals per species in each family at two selected sites in Britain

	Malham		Bangor	
	S_f	N_s	S_f	N_s
Noctuidae	86	69.03	79	10.00
Geometridae	75	90.51	103	27.15
Arctiidae	5	4.60	6	4.00
Notodontidae	4	9.75	2	3.50
Sphingidae	1	6.00	2	1.50
Other families*	1.6	16.63	2	2.33

* Five at Malham and six at Bangor.

accumulation of nightly subsamples of Macrolepidoptera collected at light, from Malham in northern England² and Bangor in North Wales, as part of the Rothamsted Insect Survey³ during 1966-72. These sites were selected from a much larger series because, in these particular instances, the relation between N_s and S_f is diametrically opposed to that given by Hebert *et al.*; the correlation is positive, not negative.

The use of selective samples to investi-

gate population properties of the kind involved here is not new⁴ and their validity is currently being investigated^{5,6}. So far, we can find no objection in principle to the technique, although the selection mechanism used to obtain a sample is obviously confounded with some behavioural properties, thus invalidating its use for certain purposes. In the present instance, the difference between our results and those of Hebert does not seem to be accountable to such artefacts and we do not question the validity of either set of data. Consequently, one must either reverse Hebert's "generally conceded" initial premise, or, following their logic, regard our result as establishing that abundance is positively dependent on competition in the Malham and Bangor communities.

As Hebert *et al.*¹ point out, we are not here concerned with replacement competition but with the diffuse competition⁷, resulting from common environmental interests⁴ and mortality factors, in which the theory of island biogeography⁸ has generated much interest. While we have good reason to regard neither experiment as conclusive, because both are partial, our positive result might seem to indicate the negative competition allowed for in Hutchinson's original niche concept⁹.

HEBERT ET AL. REPLY—Since diffuse competition in Lepidoptera, as we view it, is the result of long term coevolution among lepidopterans, their food plants, predators and parasites, we would not expect these interactions to be strong in highly disturbed communities. The importance of analysing pristine communities in synecological studies of this sort has been recognised¹. The drastic alteration of the original vegetation in Great Britain probably precludes such studies. Ter-

borgh¹, for example, worked in a rain-forest wilderness area of 20,000 km², whereas the least disturbed site in the Rothamsted Insect Survey consisted of 3.2 acres of 80-yr-old regrowth². Our main study area (Perth Road, Ontario)³ was somewhere between these extremes; within a 1-km radius of the collecting site there was little intrusion of introduced plants and forest composition approached a climax condition for the area. Beyond this distance most of the landscape was similar within a radius of 10 km, although scattered farms were present. Similarly, at our Chaffey's Locks site, much of the original vegetation remains intact.

With regard to the effect of environmental disturbance on abundance patterns

Table 1 Species abundance at Glenburnie, Ontario

	No. of species	No. of individuals per species
Noctuidae	248	51.85
Geometridae	86	25.38
Notodontidae	28	7.68
Arctiidae	27	42.15
Sphingidae	17	10.65
Other families	21	30.90

Collection was at one light during the 1969-70 season and totalled 17,226 individuals.

in Lepidoptera we have data from Glenburnie, Ontario, a highly disturbed agricultural area about 20 km from the Perth Road site. These data (Table 1) resemble those of Taylor and Woiwod in so far as there is no indication of an inverse relationship between species abundance and family size such as existed at our Perth Road and Chaffey's Locks sites. In fact at Glenburnie the Noctuidae, the largest family, have the highest mean abundance, but this is largely the result of a single species represented by nearly 6,000 individuals. The apparent direct relationship between family size and species abundance found by Taylor and Woiwod may be the result of small sample size or possibly selective sample choice, for the Rothamsted Survey collections were made at 160 sites⁴, only two of which are reported here⁵. From this same standpoint we should make it clear that we have made collections at only three sites, two in the undisturbed areas described previously³ and the remaining collection at Glenburnie.

The difference between abundance patterns in disturbed and natural habitats is probably a reflection of the increased variance in patch size, characteristic of cultivated areas in which small remnants of the native vegetation persist in the midst of a floristically depauperate agroecosystem. Often the largest patches in such heterogeneous environments

represent novel vegetation resources. For example, in south-eastern Ontario the most important elements of the agricultural grassland are introduced species⁶. Assuming the ability to use such novel resources is fortuitous, then one would expect that the species using these patches would tend to belong to the larger families of the original source fauna and, other factors being equal, these species should be overwhelmingly abundant.

We feel that confirmation of the importance of diffuse competition should only be sought in the analysis of data collected in areas where human disturbance is minimal. We predict that the effects will be most pronounced in homogeneous areas of long term stability, such as tropical rainforest, where variance in patch size is low and thus where one *a priori* expects species equitability to be high.

We thank C. C. Bower for comments.

Gravitational analogue of the magnetic force

SALISBURY AND MENZEL¹ have considered the case of a pair of charged masses separated by a distance, r , moving together at a velocity, v , in the direction perpendicular to the line joining their centres. The charges and masses were chosen so that the electrical and gravitational forces cancel one another in the moving coordinate system. Using only special relativity, Salisbury and Menzel arrived at the conclusion that the gravitational equivalent of the magnetic force is

$$\gamma^3 \beta^2 (2 - \beta^2) (G m_1 m_2 / r^2)$$

where m_1 and m_2 are the rest masses, $\beta = v/c$, $\gamma = (1 - \beta^2)^{-1/2}$, and G is the gravitational constant.

The correct special relativistic expression is arrived at as follows. The trans-

formation equations for forces are well known². The gravitational force on one of the masses, in their own reference frame, is Gm_1m_2/r^2 . In the 'laboratory' frame, with respect to which their velocity is v , the force is again along the line joining the centres of the masses and is $Gm_1m_2/(\gamma r^2)$.

An observer in the laboratory frame would find that the masses were γm_1 and γm_2 . If he calculated the gravitational force with the usual formula, he would find it to be $\gamma^2 Gm_1m_2/r^2$, which is larger than the true force by the quantity

$$X = [\gamma^2 - (1/\gamma)] Gm_1m_2/r^2$$

But X is not the gravitational equivalent of the magnetic force. If m_1 carries a charge q_1 and m_2 a charge q_2 , the magnetic force on q_2 is q_2vB_1 , where B_1 is the magnetic induction resulting from q_1 (ref. 3), or

$$\gamma\beta^2 q_1 q_2 / (4\pi\epsilon_0 r^2)$$

If q_1 and q_2 are of the same sign, the electric force on q_2 in the moving frame is repulsive, and the magnetic force in the laboratory frame is attractive. Since the gravitational force in the moving frame is attractive, the gravitational analogue of the magnetic force in the laboratory frame is repulsive. It is given by replacing $q_1 q_2 / 4\pi\epsilon_0$ by Gm_1m_2 in the expression already given, or by

$$\gamma\beta^2 Gm_1m_2/r^2 \approx \beta^2 Gm_1m_2/r^2$$

where m_1 and m_2 are again the rest masses since in the moving frame the masses are fixed with respect to one another.

The quantities γ_1 and γ_2 (see ref. 4) referred to by Salisbury and Menzel come from general relativity. They cannot be arrived at using only special relativity.

⁴ Blokland, A., *Astrophys Space Sci*, 12, 221 (1971).

MENZEL AND SALISBURY REPLY—Professor Lorrain is correct in his assertion that the gyron force between moving masses is repulsive. We show that in our paper. But, his suggestion that the transformation for magnetic forces between moving charges also applies to moving masses is incorrect. The magnetic force

between charges is proportional to the product of the equivalent currents, q_1v_1 and q_2v_2 . In our simplified presentation, v_1v_2 happens to equal v^2 . A similar identity occurs with the increase in mass caused by the kinetic energy of the motion. That increase in mass produces an extra force between the bodies. The force is proportional to the mass-current product, $m_1m_2v^2$ in our simple case, and must be distinguished from the gyron or magnetic-like repulsion.

That the magnetic force and the gyron force cannot have exactly the same coefficients should be clear from the fact that both experimentally and theoretically, electric charge is conserved under a Lorentz transformation, whereas mass increases with velocity.

The criticism that we are solving a problem in general relativity by means of special relativity is not valid. Particle accelerators demonstrate clearly that high accelerations and great mass increases occur. Thus, general relativity can be approached through special relativity; Einstein used the approach to obtain his famous law: $E = mc^2$.

General relativity theory is clearly incomplete because it predicts that mass is conserved in the same way as electric charge. The new Yilmaz theory of general relativity corrects this error and gives a conservation law of mass-energy and momentum that allows for a smooth transition between special and general relativity¹. Further, the new theory satisfies the experimental criteria.

Any form of relativity must have a firm experimental basis. The invariance of electric charge is well founded experimentally. The change of mass with velocity is known to a high degree of accuracy; it materially affects the design, operation, and observation of a wide variety of particle accelerators.

Embryonic chick tibiae in steady electric fields

WATSON *et al.*¹ report that the growth rate of embryonic chick tibiae *in vitro* is enhanced by a pulsed electric field of 1,000 V cm⁻¹ but not by a static field. We suggest that there is a simple reason why no enhancement should be expected in the static case. This has to do with the ability of the cultures to sustain a field.

Any field produced within the tissue will decay exponentially with a relaxation time constant²

$$\tau = \epsilon_0 k / \sigma \\ = 8.8 \times 10^{-12} \text{ C}^2 \text{ N}^{-1} \text{ m}^{-2}$$

where σ is the conductivity of tissue, k the dielectric constant of tissue and ϵ_0 the permittivity of free space.

There seem to be no published data on the conductivities and dielectric constants of uncalcified embryonic bone, but Schwan³ has published data on the electric properties of other tissues (for example, lung, muscle and liver). Representative values at very low frequencies (1–10 Hz) are $\sigma = 10^{-3}$ mho cm⁻¹ and $k = 10^6$. It seems reasonable that values for uncalcified chick tibia should have the same orders of magnitude. Converting σ to m.k.s. we derive a relaxation time constant $\tau \approx 10^{-4}$ s. The corresponding value for a dielectric like fused quartz is in excess of 10^6 s.

This shows why enhancement of growth is not to be expected in a steady field. During the 9-d growth period *in vitro* there is no field within the bone, no charge movement within or on the bone, and so no bioelectric command signal to the bone, except at the instants when the field is switched on or off.

Schwan's values for k may perhaps be treated with caution, but assigning more typical values to the dielectric constant (say $k = 10$) gives essentially the same result—in the steady field there is no transducer mechanism available.

Two Pergamon Review Journals of Interest to Physicists

Since January 1975 the following review journals have been available on subscription at a 20% saving in cost. This same 20% saving is offered to subscribers also on back numbers and on supplementary volumes which are occasionally published on special topics. All volumes and parts are available to non-subscribers through booksellers.

VISTAS IN ASTRONOMY

Editors: **ARTHUR BEER**, Cambridge University, England and **PETER BEER**, London

Four issues per annum, 1975 subscription rate \$50.00; two-year 1975/6 subscription rate \$95.00

Volume 19 Part 1 CONTENTS: X-Ray Astronomy, J.L. CULHANE; The Spiral Structure of our Galaxy — A Review of Current Studies, T.H. SCHMIDT-KALER; Theoretical Aspects of Galactic Research, W.W. ROBERTS Jr.; Radio-measurements of Galactic Spiral Structure, K. ROHLFS; Stellar Rings, J. ISSERSTEDT
\$18.75 £7.80 Non-subscriber price ISBN 0 08 018944 X 130pp 105 illus July 1975

Volume 19 Part 2 CONTENTS: Mathematical Background Space in Astronomy and Cosmology, S. BOCHNER; The Development of Theoretical Astronomy in the USSR, V.K. ABALAKIN; Optical Aberrations of Reflectors (The Retarding Lamina Analysis Method), C.W. ALLEN; Mars and Venus, R.M. GOODY; Optimization of Information in Astronomical Photography, N. RICHTER
\$15.00 £6.25 Non-subscriber price ISBN 0 08 018945 8 102pp 76 illus July 1975

TWO LAVISHLY PRODUCED SUPPLEMENTS

Volume 17: COPERNICUS — Yesterday and Today. Editors: Arthur Beer and K.A. Strand
Proceedings of the commemorative conference held in Washington in honour of Nicolaus Copernicus, co-sponsored by the American Association for the Advancement of Science.

ISBN 0 08 017878 2 262pp 87 illus. July 1975
Non-subscriber price \$50.00 £21.00 Special subscribers' price \$40.00 £17.00

Volume 18: KEPLER — Four Hundred Years. Editors: Arthur Beer and Peter Beer
Proceedings of sixteen International Symposia in honour of Johannes Kepler, including those sponsored by the Franklin Institute, the American Association for the Advancement of Science, the International Astronomical Union and the Academie Internationale d'Histoire des Sciences.

ISBN 0 08 017879 0 1072pp 214 illus. July 1975
Non-subscriber price \$150.00 £63.00 Special subscribers' price \$120.00 £50.00

Set of two volumes
Non-subscriber price \$175.00 £75.00 Special subscribers' price \$140.00 £60.00

PROGRESS IN QUANTUM ELECTRONICS

Editors: **J.H. SANDERS**, Oxford University, England and **S. STENHOLM**, Helsinki University, Finland
Four issues per annum, 1975 subscription rate \$30.00; two-year 1975/76 subscription rate \$57.00

Volume 4 Part 1 CONTENTS: Self-Focusing: Experimental, Y.R. SHEN; Self-Focusing: Theory, J.H. MARBURGER
\$12.50 £5.20 Non-subscriber price ISBN 0 08 018946 6 110pp 72 illus May 1975

Volume 4 Part 2 CONTENTS: Nonlinear Narrow Optical Resonances by Laser Radiation, V.P. CHEBOTAYEV and V.S. LETOKHOV
\$12.50 £5.20 Non-subscriber price ISBN 0 08 018947 4 96pp 72 illus July 1975

Volume 4 Part 3 CONTENTS: The Argon Ion Laser, M.H. DUNN and J.N. ROSS; Infrared Dispersion of Third-Order Susceptibilities in Dielectrics: Retardation Effects, C. FLYTZANIS and N. BLOEMBERGEN; Far Infrared Generation by Optical Mixing, Y.R. SHEN
\$12.50 £5.70 (approx) Non-subscriber price ISBN 0 08 019461 3 100pp (approx) October 1975

reviews

Oceanography: edge of an unfamiliar world

Courtesy Trustees of the British Museum (Natural History)

WE have become used to publishers coyly hiding the dates of publication of their books on the back of the title page; they believe, I suppose, that no one buys books when they are more than a year old. The publishers of this book* have extended the idea and concealed the fact that it is a reprint of one first published in America, by another company in 1973 (though they do say "© 1973"). This practice is dubious in relation to the purchaser; for the author, in this instance, the practice is grossly unfair. The reader looks for references to Margaret Deacon's book, which has become the standard work on the history of oceanography, and does not find them. The reason is that copies of her book only reached the US at the time that this book went to press so the author is, quite unjustly, made to seem ignorant of things one would expect to find in a book published in 1975.

The book covers the period from about 1830 to the 1970s and does not touch on the work of the 17th and 18th centuries. That is fortunate as the earlier period has been fully covered by Margaret Deacon. The opening chapters, on the early years of what eventually became the Coast and Geodetic Survey and the Hydrographic Office of the Navy, are, perhaps, the most instructive and original part of the book. There, Ms Schlee has gone back to the primary sources and one can see the back history of oddities of organisation and of disputes which lasted almost to the present time. The account of the "infamous United States Exploring Expedition" and of the shortcomings of M. F. Maury as a theorist are particularly interesting.

In the later parts of the book she demonstrates an irritating tendency to quote quite dubious and often inaccessible secondary sources when better information is easily available. For example, for an interesting quotation from

RV Challenger, one of the earliest oceanography research vessels, at Bermuda in 1873

Darwin the reader is referred to *The Darwin Reader* which contains, presumably, extracts from Darwin's works. Again, an improbable quotation from Halley is taken from *The Last Cruise of the Carnegie* where it occurs, but without any reference. Occasionally, the author is led into error by such sources: for example, Edmond Halley, with his name spelled Edmund (a form he never used in English) sails to the Antarctic in the *Paramour Pink* (a Pink is a kind of ship, not the name of a ship); both are venerable errors. The source of other errors is less clear, as when Ritter is said to have founded Scripps and to have been an "instructor in biology at the University of California at San Diego" (he was a professor at Berkeley, and UCSD was founded 60 years later by a professor from Scripps). This error is part of an eastern US and western European bias; for Ms Schlee everything west of the Ohio is Indian Country. These small errors are not of much importance but they do produce a feeling of insecurity in the reader and it is only fair to say that my doubts on several other

matters proved unfounded (for example, I doubted that St Vincent was First Lord in 1804).

The author has, perhaps, not firmly decided for whom the book is written: much of it is serious and reliable history, but in places she feels the story is getting dull and lapses into a more popular style with a wealth of irrelevant detail derived, remotely, from Hemingway and his imitators. For example: "A light snow was falling on Boston Harbour as two tugboats cast off their heavy docking lines . . ."; I am sure that she knows that it was snowing and that the lines were heavy—but that is the language of journalism rather than of history.

Perhaps I have overstressed the things that, to me, seem shortcomings; it is an interesting and readable book, contains many things that will be new to most readers and should be read by anyone with a serious interest in oceanography and the history of its development.

Some of the figures are little more than black smudges; they were only slightly better in the American edition.

E. Bullard

**A History of Oceanography: The Edge of an Unfamiliar World*. By Susan Schlee. Pp. 398. (Robert Hale: London, February 1975.) £5.

Numbers of people

Population Policy in Developed Countries. Edited by Bernard Berelson. Pp. xiii+793. (A Population Council Book.) (McGraw Hill: New York and London, 1974.) \$17.50.

THIS is a collection of essays on the present demographic situation and the policies relevant to population growth, composition and distribution in 24 'advanced' countries (including Argentina, Greece and Spain). Bernard Berelson contributes an introduction and a very sensible and comprehensive summary.

It is clear from this collection that Britain, the Netherlands and the United States are the only countries in which there has been any marked concern during the 1960s with overpopulation, and even in those countries, the concern is muted and becoming more so. In all others, the concern is more with increasing the total population or, as in the cases of Israel and South Africa, with redressing a perceived imbalance between different groups. The reasons for this are various. They include an anxiety about future manpower (even the Netherlands, although worried by high density, encourages immigration), an anxiety about political status (most evident in Argentina and Israel, but by no means absent from many other countries), and a more diffuse anxiety about the dangers of some sort of inertia from stationary or declining numbers. It is interesting that the arguments reviewed for and against rising numbers are all, without exception, inconclusive. The sanest stance is perhaps taken by the Swedes, who seem to be entirely agnostic about the reputed effects of different demographics and concern themselves instead with the maintenance and improvement of the quality of life for those who are already living.

It is also clear from these essays, however, that any country wishing to do anything about its rate of population growth is faced with considerable difficulties. Punitive policies (such as that recently introduced in Singapore) are out of the question for moral and political reasons. And less punitive policies seem to have uncertain or weak effects. There is little moral or political room for manoeuvre over mortality; providing adequate facilities for birth control is no more likely to reduce fertility than is withdrawing them likely to raise it; and although there is considerable political, if not moral, room to alter migration flows, emigration cannot be controlled easily. That leaves immigration, which many societies have used to alleviate their problems. It seems likely, however, that in all but a few cases (one of which, interestingly, seems to be Finland) the supply of

potential immigrants is drying up, and where it is not, the potential immigrants are highly undesirable.

This volume therefore gives the impression that national concerns about population are founded upon very uncertain arguments, and that even where action is considered desirable, it is rarely possible to a decisive extent. The interest, perhaps, for scientists is that so few countries pay any attention to the environmental consequences of demographic patterns. In my opinion, that attitude is correct: the connection between population and the environment is at best an indirect one; accordingly, direct measures to protect or improve the environment need be little influenced by population.

G. P. Hawthorn

Man and fire

Fire and Ecosystems. (Physiological Ecology: A Series of Monographs, Texts and Treatises.) Edited by T. T. Kozlowski and C. E. Ahlgren. Pp. xii+542. (Academic: New York and London, December 1974.) \$39.50; £18.95.

To the wildlife conservationist, fire is at the same time a valuable tool and a feared enemy, and it is this love-hate relationship which man has towards fire which forms the underlying theme of this book. It is a collection of regional essays by many eminent ecologists, most of whom are directly concerned with the practical side of forestry, range management or agriculture, and it provides a very extensive review of a subject, which demands the attention of all who are interested in the relationship between man and his environment.

Following a brief introduction there are three chapters, by Viro, Ahlgren and Bendell, of a general nature, which concern the influence of fire on soil, soil organisms, and birds and mammals, respectively. Of these the first, on soil, is very much more limited in its coverage than one might have hoped. Almost all the data quoted concerns podzols in boreal forest areas of Fennoscandia (90% of the literature quoted in the bibliography for this chapter is Scandinavian or Finnish). Although much has been contributed to our knowledge of this subject by scientists from that part of the globe, this presentation represents a very narrow approach to what purports to be a general survey of a very important aspect of the ecology of fire. The chapters on soil microbes and, particularly, on birds and mammals are, however, very full and serve as useful reviews.

There follow, in the main body of the book, sections dealing with the influence of fire on the major biomes of the world, grassland, deciduous and coniferous forests, chaparral and Mediterranean vegetation, and savanna and desert.

Apart from the chapter by Vogl on grasslands, these sections each tend to be devoted to specific geographical regions: for example, the section on forests is divided into four chapters, each dealing with one of the major forested areas of the United States. Although this system of subdivision has undoubtedly made it easier for each of the authors to concentrate on one area of the extensive literature and has also facilitated the task of editing, I feel that some potential has been lost as a result. It would have been useful if some chapters dealing with more general themes could have been incorporated, after the fashion of the first four chapters. But perhaps this attitude is inevitable in west European ecologists as their region is so markedly neglected. Given such a geographically subdivided approach, however, it is sad that space was not found for a chapter dealing with the influence of fire upon heathland and moorland ecology, a subject concerning which there is a wealth of literature. In fact, it is touched upon only briefly, for example, in Bendell's chapter where two pages are given over to the red grouse.

The final chapter, by Kayll, on the use of fire in land management, attempts the kind of synthesis which could have been profitably applied to various other topics in the book. This chapter deserved more space.

Overall, one is left with a book which covers an enormous literature and which is rich in specific examples of fire-adapted species and ecosystems from several parts of the world, but mainly from North America. North American conservationists seeking such specific information will undoubtedly welcome the arrangement of text. Those who seek more general information, however, perhaps relating to fire temperatures and influences upon succession or nutrient cycling processes, will have to collate the numerous, brief references scattered through the text. There are, however, two pervading features for which credit is presumably due to the editors: first, the emphasis upon historic and prehistoric use of fire by man in various biomes and, second, the present day value of fire as a tool in habitat management. These themes are easily traced through most of the chapters, the former reaching a splendid climax in Naveh's biblical and classical account of the history of the use of fire in the Mediterranean region.

The escalating price of this series of monographs on physiological ecology must be remarked upon. This is particularly unfortunate as it is likely to remove them from a rich potential market among nonspecialists, ecologists and conservationists, in whose hands several volumes in the series would have proved particularly valuable.

Peter D. Moore

Oceanology, meteorology and climatology

Oceanology, vol. 1. (Geophysics Series.) Edited by A. P. Kapitsa and P. S. Lineykin. Pp. 127. (Hall: Boston, Massachusetts, January 1975.) \$19.00.

Meteorology and Climatology, vol. 1. (Geophysics Series.) Edited by I. P. Danilina and A. P. Kapitsa. Pp. i+224. (Hall: Boston, Massachusetts, January 1975.) \$29.00.

THESE two books are the first volumes of a proposed series of reviews of recent scientific achievement in geophysical subjects: oceanology, meteorology and climatology, physics of the earth, glaciology, and geomagnetism and the upper atmosphere. Published by the Russian All-Union Institute for Scientific and Technical Information (VINITI) they continue the Summaries of Scientific Progress which first appeared in 1964. Chapters are contributed by Russian authorities in the relevant fields and outline briefly, with some comment, advances made in the two or three years before the original publication in Russian; the volumes thus refer to literature published in the late 1960s and early 1970s. Although the emphasis is placed on Russian work, there is also discussion of research completed in other countries.

The volume entitled *Meteorology and Climatology* includes chapters on physical, satellite and agricultural meteorology, climate and climatic change, photochemistry and the ozone-sphere, and glaciers. The *Oceanology* volume covers sea-atmosphere interaction, sea ice, sea straits, sea forecasts and oceanographic technology. This choice of topics seems somewhat arbitrary, but will probably vary in future volumes. The presentation ranges between the extremes of complete specification of the then current state of knowledge in the particular field and terse chronological summaries of recently published literature, with little reference to earlier research.

Although these works provide insight into the development of various aspects of the sciences, the publication in English some years after their first appearance in Russian rather dates the material discussed. It is felt that researchers in these fields will already be familiar with literature published, even in Russian, five years ago and that their primary interest will be historical.

But value of future volumes in the series would be greatly enhanced if a shorter delay between Russian and English publication could be achieved.

P. M. Kelly

Iron in organisms

Iron in Biochemistry and Medicine. Edited by A. Jacobs and M. Worwood. Pp. xiv+769. (Academic: London and New York, October 1974.) £15.20; \$39.25.

IRON is one of the trace elements present in mammals. It is a transition metal and as such it exists in several oxidation states and forms many metallo-protein complexes. The fascinating multiplicity of structure and function in iron compounds has been investigated by many research workers in widely separated disciplines and their efforts to elucidate various aspects of iron metabolism have yielded a vast amount of valuable information. It has become difficult to keep track of all the published data in several rapidly expanding areas of iron metabolism, but the excellent collection of reviews in *Iron in Biochemistry and Medicine* now makes this task much easier.

In this book 35 active investigators have reviewed the present state of knowledge in their particular areas of interest for the benefit of their colleagues in the same field and for those working in other disciplines. The book comprises twenty chapters, each containing a review of one topic. The topics selected all concern major aspects of iron metabolism.

The biochemistry of iron compounds is discussed in the first half of the book: the structure and function of inorganic iron, transferrin, ferritin, haemosiderin, haem, haem-proteins and non-haem iron proteins are all reviewed in great detail. The chapter on the relationship between iron and other trace metals completes the biochemical section. This is followed by reviews on the physiology and pathology of iron metabolism: iron absorption, iron deficiency and its manifestations and effects, its epidemiology and treatment, iron metabolism in infancy and childhood, the iron and the reticuloendothelial system, and iron overload. Finally, in the last three chapters, the kinetics of iron metabolism, the relationship between iron and infection, and genetic abnormalities of iron metabolism in mice are reviewed.

The book is uniformly well written, with surprisingly little repetition, a tribute to the editorial policy. Many tables and a modest number of illustrations, all thoughtfully prepared, are of great help to the reader, and the references at the end of each chapter are extensive though not comprehensive.

It is perhaps the aggregation of data from widely separated subjects which makes this book so valuable. I would certainly like to have it to hand if I needed to quote the data on iron metabolism from outside the area of my personal interest.

I strongly recommend this book as useful reading for scientists working in

this field. The clinician will find a wealth of biochemical information on the iron proteins he is trying to study by simple means in his patients. The biochemist will learn a lot about the significance of abnormalities of iron metabolism found in diseases. And I am sure that both will obtain considerable help in planning and executing future research.

B. Brozović

Hadron physics

High Energy Hadron Physics. By Martin L. Perl. Pp. xviii+562. (Wiley-Interscience: New York and London, December 1974.) £12.00.

THE nature of the strong nuclear (hadronic) interaction has been the subject of extensive theoretical and experimental investigation over the past 20 years and more, and from time to time books have appeared on aspects of this field, usually impressing upon the reader the need for further understanding of the theoretical complexities involved. This monograph by Professor Perl, an international authority in the field, helps considerably in that respect, and will be of interest and value to postgraduate students and workers at the postdoctoral level. The completion of this book, a *tour de force*, clearly required considerable stamina besides intricate academic knowledge. The author moves along with obvious energy and enthusiasm from the outset to the end, some 500 pages later, generating *en route* considerable respect for both Perl himself and his subject. Were anyone to doubt the usefulness and value of sabbatical leave, let him obtain a copy and read this book. Without such support, most practising experimental physicists would simply not have the time to create work of this quality and detail.

The standard of the book is such that the reader needs a knowledge of the basic theoretical and mathematical background material in elementary particle physics, such as one may acquire from lectures at the first year postgraduate level. Although the style of writing is often conversational, the book demands serious concentration; the considerable formal mathematical manipulation in some chapters makes the going heavy and will demand the continued perseverance of the student. I feel that the low energy nuclear or astrophysicist, who picks up this book and sees from the fly leaf that it will be an "invaluable reference" to him, could well be in deep water very soon.

The book, which contains a reasonably balanced mixture of experimental data and theory, may seem expensive but at present standards it is not excessively so. I hope, and expect, to find the book retained by science libraries for reference.

W. Galbraith

Topics in bioinorganic chemistry

Techniques and Topics in Bioinorganic Chemistry. (Aspects of Inorganic Chemistry.) Edited by C. A. McAuliffe. Pp. xv+351. (Macmillan: London and Basingstoke; February 1975.) £20.00.

THE frontier between inorganic chemistry and biochemistry has been crossed so often that the border is now ill-defined. It is too early to know how the buffer state, which bioinorganic chemistry or inorganic biochemistry may be considered to constitute, will evolve. Certainly, the subject is fashionable. But that which is fashionable is not necessarily respectable, the latter description, evocative of safe, solid virtues, being more often applied to the mainstreams of the parent subjects. But irrespective of prejudices it is impossible to ignore the importance of those elements which normally constitute the province of inorganic chemists, to biological processes. The roles of proteins containing iron and copper in all manners of redox reactions and oxygen transport are well known, and the extent to which other ions, such as zinc, are involved is slowly being revealed. Many other elements, for example, selenium, are known or suspected to be required but their functions ill-defined.

This book is one of several which have appeared recently and which seek to attract attention to the current excitement for the subject. In the first chapter M. W. Makinen attempts ambitiously to relate the functions of some proteins to structural details derived from X-ray diffraction studies occasionally reinforced by information gleaned from spectroscopic investigations. J. M. Pratt, in a chapter entitled "Principles of Catalysis by Metalloenzymes", considers the haemoglobins and myoglobins, catalase and peroxidase, and nitrogenase. The biochemical function of molybdenum is described by F. L. Bowden in a well planned review. Since the environments of molybdenum in proteins such as xanthine oxidase and nitrogenase are unknown, speculation about the role of molybdenum in these proteins is subdued. Some interesting chemistry of molybdenum is, however, included; the relevance to the biochemical function is not overstated. J. Webb discusses a number of complexes and proteins involved in iron transport and storage, with considerable emphasis on the electronic structures of the interacting iron ions. The volume is completed by an all-too-brief introduction by S. J. Ferguson to the use of nuclear magnetic resonance

spectroscopy in the investigation of the structures of proteins in solution.

Books containing chapters by different authors often suffer from two defects. First, the delay between completion of the manuscripts and publication leads, in a rapidly developing subject, to redundant speculation. Second, although the editor in his introduction seeks to justify overlap between the contents of the various chapters, this may prove irritating to those prepared to read through the book. For example, the binding of molecular oxygen to iron in myoglobin and haemoglobin is considered at length in chapters 1 and 2, as is nitrogen fixation in chapters 2 and 3. But as it is likely that the volume will be used as a source of review articles, this criticism may not be pertinent. **H. A. O. Hill**

Eucalyptus jucunda C. A. Gardner, usually 2–3.5 m, but sometimes up to 8 m high. Photo shows stamens and elliptical fruiting bodies (1.5 × 1.2 cm). Taken from *Eucalypts of the Western Australia Goldfields* by G. M. Chippendale. Pp. iv+216. (Australian Government Publishing Service: Canberra, 1973.) AS\$3.75.

Casting light on structures

Biochemical Spectroscopy. By Richard Alan Morton. Vol. 1: pp. xvi+1–381; vol. 2: pp. 382–873. (Adam Hilger: London, March 1975.) £80.00 for set.

THE title *Biochemical Spectroscopy* may today conjure up an image of a work dealing fairly exhaustively with the practical and theoretical aspects of the spectroscopy, primarily, of current molecular biology. It might, for instance, emphasise the applications in that field of the more modern techniques of ESR, Mössbauer and NMR, and perhaps give as much weight to

circular dichroism, optical rotatory dispersion and Raman as to the older basic techniques.

This book is, however, of a quite different kind. Essentially, it consists of a large number of monographs, grouped rather arbitrarily into longer sections. Of these, some, like those entitled 'Water and Sunlight in a Biological Context' and 'Electronic Absorption Spectra', give background material of a relatively generalised kind but most of them are groups of monographs, many quite short, on classes of natural products and the light that spectroscopic methods have cast (and in a few cases might yet cast) on their structures, functions and interrelations. The range of topics is wide, and it is revealing to see in how many and diverse fields the author has himself made contributions in a laboratory career lasting 50 years. A chemist with no special interest in spectroscopy could do worse than to turn first to this book if he should have to deal with a natural product belonging to a known but unfamiliar class; the treatment of the chemistry is always interesting, if necessarily incomplete, and the references are excellent. The writing is clear and straightforward, and, though the bias is towards classical visible and ultraviolet spectroscopy, developments based on other techniques are not neglected.

In places the reader encounters unexpected hurdles, however. Some of these arise from a failure to number, and thus to correlate with the text, the numerous structural formulae embedded in it, and in places the lack of either names or reference numbers, coupled with a sprinkling of errors, makes the going hard indeed for a reader unfamiliar with the field. The sources of much of the tabulated data are not given, and some sections wear the antique look which is conveyed by the bulgy contours of 30 or 40 year-old spectral diagrams; these, however, normally occur where the more modern data which might otherwise supersede them are incomplete. Although in places some updating of material is surely needed, a prime defect is the plethora of small errors and misprints which defaces this handsomely produced—and extremely expensive—pair of volumes.

The price is such, in fact, that the volumes can only be considered as a library reference work. This is a great pity, since a deal of pleasure and information is to be had from random browsing. It is, however, clearly impossible to suggest cuts and economies in presentation which could result in a price reduction by the order of magnitude which is needed to make the volumes as accessible as they deserve to be. **E. A. Johnson**

announcements

Award

The **Kelvin Gold Medal** has been awarded to **C. S. Draper** for his work on the problems of guidance and control in space.

Appointments

R. C. Newman has been appointed Professor of Physics at Reading University.

D. Givol has been named the first incumbent of the Altschuler Chair of Immunochemistry.

J. D. Gillett has been appointed the first Pro Vice-Chancellor of Brunel University.

Miscellaneous

Culture Collections. The United Kingdom Federation for Culture Collections, designed to assist microbiologists, is now in existence. Further information can be obtained from Dr I. J. Bonsfield, Torry Research Station, PO Box 31, 135 Abbey Road, Aberdeen, Scotland.

International meetings

September 29–October 1, **Biological implications of metals in the environment**, Richland, Washington (Miss J. H. Rising, Biology Department, 331 Building, Battelle-Northwest, Richland, WA99352).

October 7–9, **Techniques for the microbiological examination of foods, pharmaceutical and cosmetic products**, London (Scientific Symposia Ltd., 121 King Street, London W6 9JG, UK).

October 20–24, **Clean air and pollution control**, Brighton (The Secretary, National Society for Clean Air, 136 North Street, Brighton BN1 1RG, UK).

October 29–November 1, **Chemical evolution of the early precambrian**, Maryland, US (Dr Cyril Ponnamperna, Laboratory of Chemical Evolution, Department of Chemistry, University of Maryland, College Park, Maryland 20742).

October 25–29, **Medical radionuclide imaging**, Los Angeles (The Secretary, International Atomic Energy Agency, PO Box 590, A-1011 Vienna, Austria).

October 27–31, **Heavy metals in the environment**, Toronto (Mr K. Ward, Executive Secretary, National Research Council of Canada, Ottawa, Canada K1A 0R6).

Person to Person

Printing of mathematics. Could anyone loan or sell me a copy of *The Printing of Mathematics* (Oxford, out of print)? Also any other books on mathematical printing. Will pay postage. Vic Cresswell, Dawkins Typesetters, Graphic House, Southwark Street, London SE1 or (01)-407 7525.

Seeds and latex. Investigator will appreciate knowing where to obtain seeds and latex (1–2 kg of each) of *Hura crepitans* (*Hura brasiliensis*) (Professor F. Stirpe, Istituto di Patologia generale, Via S. Giacomo 14, 40126 Bologna, Italy).

Endoplasmic reticulum. Biologists writing a book on the structure of living cells would be grateful to know of any publications which have indicated that the endoplasmic reticulum might be an artefact. (Dr H. Hillman and Mr P. Sartory, Unity Laboratory, Department of Human Biology, University of Surrey, Guildford, Surrey GU2 5XH).

There will be no charge for this service. Send items (not more than 60 words) to Holly Connell at the London office. The section will include exchanges of accommodation, personal announcements and scientific queries. We reserve the right to decline material submitted. No commercial transactions.

October 30, **Recent chemistry of natural products, including tobacco**, Richmond (Nicholas J. Fina, The Phillip Morris Research Center, PO Box 26853, Richmond, Virginia 23261).

October 30–31, **Comparative biology of skin**, London (Dr R. I. C. Spearman, The Zoological Society, Regent's Park, London NW1 4RY, UK).

Reports and publications

Great Britain

Timber Research and Development Association. Annual Report for 1974. Pp. x+16. (High Wycombe, Bucks: Timber Research and Development Association, 1975.) [27]

1975 Conference on Dielectric Materials, Measurements and Applications, 21–25 July 1975, Churchill College, Cambridge. (Organized by the Science, Education and Management Division of the Institution of Electrical Engineers, in association with the Institute of Electrical and Electronics Engineers (United Kingdom and Republic of Ireland Section); the Institute of Physics; and the Institution of Electronic and Radio Engineers.) Pp. xii+336. (London: The Institution of Electrical Engineers, 1975.) [27]

Explore the New Forest. Edited by Donn Small. (An official guide by the Forestry Commission.) Pp. 125. (London: HMSO, 1975.) £1.85 net. [37]

Philosophical Transactions of the Royal Society of London. A: Mathematical and Physical Sciences. Vol. 278, No. 1286: The Influence of Pore-Water Tension on the Strength of Clay. By A. W. Bishop, N. K. Kumapley and A. El-Ruwaihi. Pp. 511–554 + Plate 17. UK £3.95; Overseas £5.10. Vol. 278, No. 1287: The Initial-Value Problem for the Korteweg-de Vries Equation. By J. L. Bona and R. Smith. Pp. 555–604. UK £1.95; Overseas £2. (London: The Royal Society, 1975.) [37]

The Lister Institute of Preventive Medicine. Report of the Governing Body, 1975. Pp. 22. (London: The Lister Institute of Preventive Medicine, Chelsea Bridge Road, SW1, 1975.) [47]

Association of the British Pharmaceutical Industry. Annual Report, 1974/75. Pp. 44. (London: Association of the British Pharmaceutical Industry, 162 Regent Street, 1975.) [77]

Potato Marketing Board. Machinery Directory. Pp. 44. (London: Potato Marketing Board, 50 Hans Crescent, SW1, 1975.) 15p. [87]

Rowett Research Institute. Annual Report of Studies in Animal Nutrition and Allied Sciences, Vol. 30, 1974. Pp. 143. (Bucksburn, Aberdeen: Rowett Research Institute, 1975.) £1; \$2.30. [87]

National Vegetable Research Station. 25th Annual Report 1974. Pp. 166. (Wellesbourne, Warwick: The British Society for the Promotion of Vegetable Research, National Vegetable Research Station, 1975.) £1.25. [107]

Bulletin of the British Museum (Natural History). Geology, Vol. 26, No. 2: The Shell Structure of the Liassic Ammonite Family Dactyloceratidae. By M. K. Howarth. Pp. 45–67 + 10 plates. (London: British Museum (Natural History), 1975.) £2.70. [107]

Proceedings of the Royal Irish Academy, Vol. 75, Section A, No. 10: Luminescence from Chromium Doped Yttrium Aluminium Garnet. By M. O. Henry, J. P. Larkin and G. F. Imbisch. Pp. 97–106. 35p. Vol. 75, Section B, No. 15: The Distribution and Morphometried of Spittle Bugs on Irish Blanket Bog. By N. Nixon, Elaine F. Okely and Ruth M. Blackith. Pp. 305–315. 29p. (Dublin: Royal Irish Academy, 1975.) [107]

Philosophical Transactions of the Royal Society of London. B: Biological Sciences. Vol. 271, No. 911: A Discussion on Forests and Forestry in Britain. Organized by G. D. Holmes, P. F. Wareing and J. L. Harley. Pp. 45–232. (London: The Royal Society, 1975.) UK £7.75; Overseas £7.95. [107]

European Spectroscopy News, Vol. 1, No. 1, 1975. Pp. 1–32. Edited by P. M. Williams. Published Bimonthly from July 1975. (London: Heyden and Son, Ltd., Spectrum House, Alderton Crescent, NW4, 1975.) Free to all Practising Spectroscopists. [107]

London and Home Counties Regional Advisory Council for Technological Education. Science Education in the Region, 1975/76. Pp. 55. (London: London and Home Counties Regional Advisory Council for Technological Education, 1975.) 70p. [147]

Responsibilities of Industry in the Field of Health. By Dr. J. H. Briggs and Dr. Robert Murray. (Foundation Dialogues.) Pp. 16. (London: Foundation for Business Responsibilities, Portland House, Stag Place, SW1, 1975.) 25p. [157]

Union Internationale des Laboratoires Independants. Register of Members 1975. Pp. 237. (London: Union Internationale des Laboratoires Independants, Ashbourne House, Alberon Gardens, NW11, 1975.) [157]

Freedom and Restraint in Broadcasting: The British Experience. By Sir Michael Swann, FRS. (The 'Queen' Lecture given in the Kongresshalle, Berlin, 29 May 1975.) Pp. 31. (London: BBC, 1975.) [157]

Public Health Laboratory Service. Monograph Series No. 8: Isolation of Salmonellas. By R. W. S. Harvey and T. H. Price. Pp. 52. (London: HMSO, 1974.) £1.50 net. [157]

No easy way to solve universities' problems

IN 1970 the number of students entering universities in the United Kingdom to study dentistry (1,170) was a mere third of the number planning to study chemistry. The 1974 entry was somewhat different, according to the statistical supplement to the Twelfth Report of the Universities Central Council on Admissions (UCCA). There were 3,065 prospective dentists, one and a half times the number of prospective chemists. Provisional figures for 1975 show the trend halted, but no more.

This is the most extreme example. The swing would be somewhat less if, say, medical students and physicists were compared, but the point must surely now have penetrated the consciousness of even the most optimistic or ostrich-like scientists: that a totally unplanned manpower shortage of scientists is creeping up on us.

Ironically, at the same time an equally unplanned shortage of job opportunities within universities has arisen, with the unwillingness of most universities to take on long term staff commitments during the past two years. It would be incorrect to see these two shortfalls balancing each other out and so preventing the worst from happening; only a small fraction of university entrants eventually opt for a university career. The universities are in trouble, and university science is in the most trouble of all.

It is against this depressing backdrop that the House of Commons Select Committee on Science and Technology issues its interim report on the short-term problems of scientific research in British Universities (House of Commons Paper 504, HMSO, 65p). Nothing in the report will be a great surprise; the committee has not fallen for any one witness nor has it advanced any patent remedy of its own. Instead there is a sober assessment of the situation and some muted pleas to the Department of Education and Science and the University Grants Committee to hold the line on the balance between teaching and research in universities and to the universities to look carefully at their individual priorities.

Research in universities looks a precariously marginal activity when viewed from Whitehall. The Department of Education and Science is very dominantly a department of education. The University Grants Committee sees research and educational elements as indistinguishable when it allocates money, but reckons research only to comprise "rather more than 25%" of the totals. The research councils put less than one-third of their money into university departments by way of grants, studentships and fellowships. In every way university research is vulnerable to the stirrings of its larger administrative

bedfellows. Some of those bedfellows, such as academic salaries, not only rightly take precedence, but also may be committed for the next 10, 20 or more years.

And yet a crisis need not be a bad thing, particularly in an environment which has known nothing but growth for years. The committee itself remarks that if inflation concentrates university minds, it may be of some benefit. The opportunity to review priorities and seek the most efficient means of deploying more limited funds is one which it would be "highly regrettable" for the universities to ignore. Linked to this broad hint is a similar one that universities must review the relevance of their research activities. This statement is a bit of a compromise; there was at one time within the committee a feeling that there should be a national body—perhaps a 'de-grants committee'—to perform this function. And it is made clear that this idea is only temporarily on ice.

Can and should the universities respond to such a challenge to assess their priorities both in general and in terms of relevance? The answer is almost certainly that individually they lack the tools to do so or indeed much perception of how to assess relevance. The vice-like grip of job security so severely restricts the universities' freedom of action that opportunities for change, redeployment or tapering off in the staffing of departments is restricted, even in good times, largely to the arbitrariness of death, resignation or retirement. Certain economies are no doubt still possible by sharing of facilities and so on, but when 80% or more of the universities' general funds are committed to salaries and wages it is clear that the scope is limited if personnel levels are maintained.

Even more difficult to respond to is the challenge that universities must review relevance. First, there would certainly be sniping across the great divide between arts and sciences; is mediocre electrical engineering less or more relevant than competent Old Testament theology? Second, some of the relevancies can only be seen in a national perspective; maybe mathematical geodesy or Amharic look pretty irrelevant in a local context, but maybe there is a national need for a few graduates a year. Third, demands for relevance could lead to the sight of academics presenting unedifying inflated and misleading claims for their work rather in the way that confessions are 'volunteered' in some countries.

The committee rightly identifies the principal crisis as one of confidence in the future. A veiled threat to review relevance before the committee does it for you will hardly bolster this confidence. □

THE POOR CLIMBING BOYS.

A HUMANE British Parliament passed an Act several years ago, known as Lord Shaftesbury's "CLIMBING BOYS' ACT," whereby the barbarous employment of poor children for sweeping chimneys was prohibited, and the use of machines enforced. So far as London is concerned, this Act is, we believe, faithfully enforced,—but in the provinces there are at the present time upwards of 3000 of these poor creatures still suffering the wrongs of British slavery.

As the bulk of the climbing boys come from the families of working-men, who by accident, or the premature death of their parents, are thrown into Union Houses—we appeal to our readers to do what they can to enforce the faithful carrying out of the Act of Parliament. Mr. Wm. Wood, of Bowden, Manchester, or Mr. James Glass, of 24, Barrington Crescent, Brix-

"PITY THE POOR CLIMBING BOYS!"

ton, will gladly correspond with any parties who desire to aid in preventing the use of climbing boys in districts where they are at present employed.

Cancer at work

Although there has been progress in the treatment of cancer by radiation, surgery, chemotherapy and immunotherapy, it is probable that efforts to prevent the disease have been more rewarding and effective than those made to improve treatment. Some occupational cancers can be prevented when the cause is identified. It is, however, often difficult to find the causes and sometimes even more difficult to remove them when they are known. Two hundred years after Percival Pott made the connection between cancer and the working environment, Professor E. Boyland reviews subsequent work on occupational cancers.

PERCIVAL POTT, FRS, was a surgeon at St Bartholomew's Hospital; his "Chirurgical observations relative to the cataract, the polypus of the nose, the cancer of the scrotum, the different kinds of ruptures and the modification of the toes and feet" was published by Hawes and Collins in Pater-noster Row in 1775. The paper entitled "cancer scroti" describes "a disease as peculiar to a certain set of people which has not, at least to my knowledge, been publicly noticed; I mean the chimney-sweepers' cancer". "The trade call it soot-wart. The disease, in these people, seems to derive its origin from the lodgement of soot in the rugae of the scrotum". He had identified a cause of cancer—a carcinogen active in man. The observations and identification did not stop the exposure of the child chimney sweeps, and Charles Kingsley, who was an active member of the Christian Socialist movement led by Frederick Denison Maurice, described the plights of these child workers in *Waterbabies* almost a century later.

Pott pointed out that "the subjects are young, in general in good health, at least at first, the disease brought on them by their occupation—all this makes it (at first) a very different case from cancer which appears in an elderly man, whose fluids become acrimonious from time, as well as other causes; or from the same kind of complaint in women who have ceased to menstruate. But be all this as it may, the scrotum is no vital organ, nor can the loss of a part of it ever be attended with . . . the smallest degree of inconvenience". He must have perceived the process which is chemical carcinogenesis.

Percival Pott was a modest scholar; as his son-in-law, Sir James Earle, wrote "he often said he began to teach when he had much to learn; and that he was not actuated by that opinionative wisdom which sometimes attends advanced life, after all his study and experience he confessed that he still retained a long list of inquirenda". Samuel Johnson was one of his patients and his portrait painted by Joshua Reynolds hangs in St Bartholomew's Hospital. His epitaph reads "The labours of the ancients were familiar to him; he scorned to teach a science of which he had not traced the growth."

The Romans had chimneys in connection with their hot air heating systems, but in northern Europe chimneys were developed slowly. In mediaeval times hearths in the centre of the living room and vents in the roof were usual. When coal became available as a domestic fuel Count Rumford established the forms and proper relationships of the parts of the chimney. The

chimneys which required children to clean them were an English development and the associated disease was more common in England than in continental Europe. It seems probable that chimney sweeps in Germany had some form of protective clothing.

Before Percival Pott, Ramazzini in the *de morbis artificum*, published in 1700, considered occupational diseases such as the colic due to lead to which painters, glaziers and plumbers were exposed. Ramazzini had noticed the high incidence of breast cancer in nuns and indicated that this was caused by their occupation.

Following the work of Pott many clinicians reported on the condition. Bell in 1794 described other cases and said it appears obviously to be produced by soot, for it is found that besides chimney sweeps those who are employed in manufacture in which soot enters are occasionally seized by it. James Earle in 1808 recorded a case of a gardener with epithelioma of the left hand on which he had previously hung a pot containing soot used to kill slugs. He saw that skin cancer elsewhere than in the scrotum could be caused by soot. In the edition of the works of Percival Pott, revised by James Earle in 1808, reference was made to an eight-year-old apprentice with scrotal cancer. Often, however, there was a long latent period. Curling in 1856 described a case of a sailor who developed scrotal cancer in the fifth decade of life but who had been brought up as a sweep. In the nineteenth century the disease remained but it was recognised that not all children employed as sweeps developed scrotal cancer.

With the expansion of the Industrial Revolution increasing amounts of oils were used for the lubrication of machines. Before 1850 the oils were mainly of animal origin but later mineral oils were used in much larger quantities. Volkmann in 1875 described occupational skin cancer by tar, paraffin and soot in Germany and in the following year (1876) Bell of Edinburgh described cases of "paraffin cancer" in workers in the Scottish shale oil industry.

As the incidence of chimney sweeps' cancer decreased in the nineteenth century the incidences of scrotal cancer increased among the spinners of the Lancashire cotton industry, the first cases being described in 1887. This "mule spinners' cancer" has decreased in the present century because (1) the cotton industry employs fewer workers, (2) ring spinning machines have replaced the old mule spinners, (3) less carcinogenic oils controlled by specifications are used, and (4) there has been a general improvement in hygiene. Although less common, scrotal cancer

still occurs in industry in conditions in which men are exposed to lubricating oils.

Although the first synthetic dyestuffs were made in England by Perkin, the German chemical industry was the first to exploit the discoveries and manufacture dyestuffs on a large scale. It was in Germany that the first cases of bladder cancer due to exposure to aromatic amines were reported by Rehn in 1895. The development of dyestuffs industries in other countries was associated with widespread increases in the incidence of bladder cancer. Cases of bladder cancer in men who had manufactured dyestuffs intermediates including 2-naphthylamine and benzidine in England were reported by Wignall in 1929. Another aromatic amine, 4-aminobiphenyl, had been manufactured and used in the United States for many years. The intelligent anticipation and laboratory work of Williams and his colleagues (1952), showing that it was carcinogenic to animals, prevented the manufacture of this compound in Britain and other countries. In 1955 evidence was presented showing that this compound had caused cancer in men occupied with its manufacture.

In addition to their use in dyestuff manufacture, aromatic amines were used in the rubber industry. Case and Hosker in 1954 found an increased

Pott by Reynolds (courtesy Bart's Hospital)

incidence of bladder cancer in rubber workers in one region of England. It is probable that carcinogenic aromatic amines have not been used in the rubber industry since 1950 and because of the possible hazard special facilities for early diagnosis have been available for 20 years. Cancer of the bladder has been a prescribed disease in Britain since 1953.

Early in the present century Japanese workers demonstrated that the application of coal tar to the ears of rabbits or the skin of mice induced tumours some of which were malignant. This provides a bioassay of carcinogenic activity which Kennaway and his colleagues used to identify the hydrocarbon 1, 2,5, 6-dibenzanthracene as the first known compound to induce cancer and then for the isolation and characterisation of 3, 4-benzopyrene from coal tar. Carcinogenic aromatic amines and polycyclic hydrocarbons were known 40 years ago, but in spite of much research the mechanisms by which they exert their carcinogenic actions are still not exactly known.

The knowledge of the chemical nature of the carcinogens, which must have been present in the soot that caused cancer in the young chimney sweeps described by Percival Pott, has in some cases helped with the problems of reducing the hazard of environmental carcinogens. Many other extrinsic cancer-producing agents have been discovered. As most cancers in man are probably caused by extrinsic factors, many still remain to be identified. The discovery of these and the removal or reduction of them in the environment will decrease the incidence of cancer in the way started by the English surgeon two hundred years ago. □

THE young scientist who wants to venture into medical research now faces an acute problem in finding a satisfactory career structure. It used to be that workers in this field had some form of tenure, either through their contract or through a moral obligation readily acknowledged by the employer. But the trend in recent years has been to offer only temporary appointments lasting, at most, five years. This poses severe problems.

The really outstanding person will always find help elsewhere if the support runs out, of course. My concern is more for the capable and well qualified scientist. Three to five years of medical research may actually prove to be a handicap when competing for teaching or research posts with candidates who have pursued a more academic path.

The Medical Research Council have recently recognised the problem in their own establishments by ensuring that tenure will be granted to staff no later than in their mid-30s—other institutions will probably fall into line. But this only accounts for 20–30 people annually. Numerous first-rate scientists better equipped for work in applied medical research are still un-

helped by this scheme.

In the UK, experience has shown that the best way to effect the transition from research activity to clinical trials is through a team of medical and scientific staff who can meet

Career medicine

regularly on an equal footing. (Contrast this with the United States where young doctors may undergo a long training in basic science and later become competent to direct highly advanced work in a hospital laboratory.) Such teams at present exist in advanced institutes and in them the scientist (who often makes the early running) has learnt to communicate successfully with the clinician. Might not such teams be introduced more widely in medical schools and general hospitals? They could be a highly efficient means of speeding the acceptance by clinicians of the most recent advances in laboratory methods. And might not this be a solution to the career problem for medical scientists?

Such a scheme could best start in specialised centres or medical schools where there already is a tradition of regular clinical conferences. Young medical staff would rapidly recognise the advantages of team work with scientists; it is all but impossible to keep pace with advanced laboratory methods as well as advanced medicine.

Recruitment of scientists to such a service could take place in two ways. Firstly, at the graduate level, for which the Universities might set up an M.Sc. course in Bio-Medical Science as a recognised qualification. Secondly, scientists who have already spent three to five years in medical research might be required to take a diploma in Bio-Medical Science. These courses would provide a general clinical background to the problems in which the hospital laboratories play a major role a large proportion of the lectures being given by medical staff. This would be far less expensive for the country than the training of medical graduates in advanced laboratory methods, in addition to their medical training. Such a scheme could provide a career structure for those scientists at present in medical research who have a most uncertain future.—E. J. Ambrose.

international news

As Britain prepares to face another winter with further rises in the price of fuel, the Department of Energy, formed less than two years ago to deal with the problems of energy crisis, has become the target of heavy criticism in a report prepared by the House of Commons Select Committee on Science and Technology (House of Commons Paper No. 487, HMSO, 1975). Among the proposals contained in the report is a call for new administrative machinery at Ministerial level to co-ordinate a policy intended to cut Britain's annual energy bill by £1,000 million (about 15%).

According to the chairman of the all-party committee, Mr Arthur Palmer, a reorganisation is needed because of the failure of the present energy administration to implement policies of energy conservation effectively. He said last week that very little had been done during the past year to improve energy efficiency and that the committee did not share the government view that the recent diminution in energy demand, largely attributable to the recession, represented a genuine saving. The problem of energy conservation, he said, had not been considered with sufficient urgency by the existing administration, apparently because of the tendency in government circles both to treat issues requiring practical and administrative attention in an abstract and political manner, and to consider important long term issues only in the light of their short term political implications.

In all, the report lists 42 recommendations for increasing efficiency in the use and supply of energy. Underlying the proposals is a recommendation that a full time "task force" of Ministers, officials and outside experts be set up to meet the problems of the continuing energy crisis. If the government decides to act on the committee's proposals after the report has been considered by Parliament, the new administration would replace the Advisory Council on Energy Conservation (ACEC) and the Advisory Council on Research and Development (ACORD) both of which are responsible to the Department of Energy at present. Nonetheless, that would not mean the demise of the Department of Energy itself, which would remain responsible for the more specific problems of coal, offshore oil and gas and nuclear power. Indeed, the report notes

British energy savers taken to task

by Allan Piper

that it may be the department's involvement with those matters that has led to what is seen as a lack of central direction and decisiveness in matters of conservation.

If it set up, the main function of the task force will be to ensure a greater efficiency of energy use in every area of the economy. Operating on its own budget, it will work within a time limit towards clearly defined objectives. On the basis of the information collected from expert witnesses interviewed during the preparation of the report, the committee suggests that a realistic target is a reduction in energy consumption of 15% within three years. That could be achieved, according to the report, "without sacrificing output, employment, or living standards". Additionally, the report further points out that an effectively directed programme of energy conservation could be sustained at a lower cost than the development of an equivalent amount of additional energy from North Sea resources.

The effectiveness of the task force will, it is hoped, rest mainly in its regional structure. Recognising the need for a more direct implementation of policies than there has been in the past, the committee believes that future policies can only be successful if the task force establishes a strong local organisation.

Exactly how the task force will fit in with the Department of Energy is not entirely clear, however, though the committee recommends that it should be set up at Ministerial level and should report directly to the Prime Minister. Questioned on the purpose of establishing another administrative body in addition to the Department of Energy, Mr Palmer said the committee felt it was necessary because the problems of energy conservation cut across existing departmental boundaries. As an example, he cited the Department of Industry and the Ministry of Defence.

Both, he said, are in need of effective policies of energy conservation, but neither falls within the jurisdiction of the Department of Energy. The new administration, on the other hand, would possess sufficient political status to implement effective policies wherever necessary.

On the industrial front the report calls for the introduction of a new grants scheme that should be particularly favourable to smaller interests and is designed to encourage the introduction of more efficient plant. Industry accounts for about 40% of British energy consumption, and the wastage is particularly high. It therefore seems likely that the committee's call for legislation to cover the industrial use of fuels and the running of industrial equipment will receive serious consideration. Furthermore, the benefits to be gained by using the experience of independent consultants on energy-saving schemes is recognised in the report, and the committee suggests that they could be suitably employed as agents by the task force. In the committee's view the National Industrial Fuel Efficiency Service (NIFES), the largest consultant organisation in the field, with 136 engineers, would be particularly well equipped to cope and could, even, be reintroduced advantageously to the public sector.

The committee has listed several recommendations for preventing domestic energy wastage and profligate use of energy in the areas of public and private transport. The report suggests that new buildings should be constructed to a specific standard of insulation, with legislation introduced to ensure the implementation of minimum requirements within the home. There is also a call for the maintenance of advertising campaigns to impress on the public the need for a greater awareness of the continuing energy crisis. In that respect the Department of Energy is criticised for its past record and is accused of following a policy "feeble in contrast to the need for strong action". One recommendation that seems long overdue is that the energy supply industries—the electricity and gas boards—must reconsider the scheme whereby consumers pay proportionally less for additional consumption beyond a certain point.

On the question of transport the committee makes the interesting suggestion that inland waterways and

As an example of how not to regulate environmental chemicals, the case of diethylstilboestrol (DES) is a tough one to beat. A feed additive which stimulates growth in cattle, DES has been enmeshed in bitter controversy for more than a decade. The problem is that DES is highly carcinogenic, and traces of it can sometimes be found in meat and beef liver. Consequently, after bending over backwards for years in an effort to find a way to keep DES on the market the Food and Drug Administration (FDA) in 1973 issued an order banning its use. But the ban was thrown out in court because the FDA had ineptly failed to follow the correct procedure when it passed sentence. The result is that DES is still on the market and is now found in beef liver at higher concentrations than when it was banned two years ago.

That sorry series of events prompted the Senate last week to pass an unprecedented bill banning the use of DES in cattle feed, at least until the FDA can prove that it is safe. If the House of Representatives follows suit—prospects there are uncertain—it will be the first time that Congress has legislated against a single chemical.

The case against DES is a complicated one, which involves weighing the potential risks of long term exposure to extremely low levels of a known carcinogen against the economic benefits of bringing cattle to market more quickly. It is not something at which politicians are particularly adept, and the debate certainly proved that the floor of the Senate is not a particularly good place to reach complex regulatory decisions.

Diethylstilboestrol is one of the few chemicals for which there is good evidence that it causes cancer in man. Recently there have been a number of cases—220 have come to light so far—of an extremely rare vaginal cancer in young women in their late teens and early 20s; a common factor among the women is that their mothers took DES as a drug during the late stages of pregnancy to prevent miscarriage (a practice now discontinued). With such evidence at hand, there is good reason to keep DES out of foods.

But DES is an extraordinarily good growth stimulant for cattle, and it originally seemed that if it was withdrawn from cattle feed a few days before the beasts were slaughtered, it would all be excreted and no residues would contaminate the meat. Things did not work out like that, however, because in spite of FDA regulations

Washington seen

by Colin Norman

requiring cattle to be taken off DES at least a week before slaughter, residues continued to show up in beef and liver.

The levels at which it is present are, however, extremely low, and here the discussion gets into the controversial area of whether or not there is a threshold dose of a carcinogen below which it presents no health hazard. The Senate debate proceeded with those supporting a ban, led by Senator Edward M. Kennedy, citing a sheaf of reports suggesting that known carcinogens should be kept out of the environment completely, while opponents of the ban argued that DES is present in meat at such lower levels that it poses no risk. In the end, the ban was approved by a vote of 61 to 29, and everybody was left wishing that the FDA had been less inept when it first tried to ban DES.

● Acting with a degree of unanimity that is rare in the top echelons of the scientific community, 186 eminent scientists have endorsed a statement condemning astrology as pernicious, anti-scientific nonsense based on magic and superstition. Published in the September/October issue of *The Humanist*, the journal of the American Humanist Association, the statement notes that astrology "pervades modern society" and suggests that "the time has come to challenge directly, and forcefully, the pretentious claims of astrological charlatans".

Proceeding from the observation that "in ancient times people believed in the predictions and advice of astro-

logers because astrology was part and parcel of their magical world view ... [and] they had no concept of the vast distances from the Earth to the planets and stars", the statement notes that "now these distances can and have been calculated, we can see how infinitesimally small are the gravitational and other effects produced by the distant planets and the far more distant stars". Consequently, "It is simply a mistake to imagine that the forces exerted by stars and planets at the moment of birth can in any way shape our futures. Neither is it true that the position of distant heavenly bodies can make certain days or periods more favourable to particular kinds of action, or that the sign under which one was born determines one's compatibility or incompatibility with other people".

The statement was drafted by Bart J. Bok, Emeritus Professor of Astronomy at the University of Arizona, Lawrence Jerome, a science writer, and Paul Kurtz, Professor of Philosophy at the State University of New York at Buffalo. It was sent to about 300 scientists, chiefly astronomers and astrophysicists, during the summer, and about 60% of them responded positively. Among the signatories are 18 Nobel Prizewinners.

Given the eminently sensible and unarguable contents of the statement, it is not surprising that it attracted so much influential support. But why was it deemed necessary to open a frontal assault on astrology at this point in time? Kurtz said last week that he is disturbed by the burgeoning interest in astrology, particularly in the United States (where, according to one estimate, there are some 20,000 practising astrologers), and Bok noted in a separate article in *The Humanist* that some universities and junior colleges even offer courses in astrology. The statement itself also condemned "the continued uncritical dissemination of astrological charts, forecasts and horoscopes by the media and by otherwise reputable newspapers, magazines and book publishers [which] can only contribute to the growth of irrationalism and obscurantism".

coastal shipping routes should receive more extensive use than at present. Perhaps alarming to the private motorist will be the call for consideration of severe restrictions on the use of private transport in one or two selected cities—Mr Palmer mentioned Bristol, his home constituency as a suitable example. Mr Palmer also mentioned the committee's suggestion that companies should establish car pools rather than provide individuals with cars.

As for the less immediate future, the government is urged to consider the use of alternative sources of energy such as nuclear fusion and hydrogen fuel. Significant to that proposal is the recommendation that the Energy Technology Support Unit (ETSU), at Harwell, primarily responsible for research into new energy projects under the leadership of the Department of Energy's Chief Scientist, Dr Walter Marshall, should be expanded and

strengthened by the task force. Mr Palmer also mentioned what he referred to as "way out" sources, and said that in particular the committee had been interested by the idea of tidal power. The Severn Estuary is in fact well suited to provide energy from that source and has already been the subject of several research schemes. Presumably, solar energy and wave power will also come under scrutiny if the committee's proposals are adopted. □

THE right of the government of the host country to an international conference to refuse entry visas to foreign delegates has long been a vexed one. The Tbilisi conference on artificial intelligence (September 2–8) produced an interesting variation on this problem: the right of the government of the host country to refuse to admit its own nationals.

The problem in this case was that of Jewish refusnik scientists, still living within the Soviet Union but dismissed from their academic posts while awaiting a visa for Israel. Although the Soviet scientific hosts of the conference were quite willing to admit them, the KGB was totally opposed to this and considered their wish to attend as being a "provocation". The international organising committee, however, made strong representations that, should these scientists be refused permission to attend, there would be forceful protests and resulting adverse publicity. Consequently, for fear of a withdrawal by the USA and other Western delegations, and as a result of last minute meetings in Moscow, the authorities decided to permit Dr Aleksandr Lerner to travel from Moscow to attend the conference. He was escorted to Tbilisi by the same KGB officer who had formally told him he could not go and welcomed by the head of the Cybernetics Institute of the Georgian Academy of Sciences, Dr V. V. Chavchanidze, who had himself photographed pinning on Lerner's conference badge. Although subjected to a certain amount of official surveillance throughout the conference, Lerner was able to circulate freely among the delegates and take part in

a panel session "Cybernetics, Mathematics and Artificial Intelligence".

Less fortunate were the Gold'shtein brothers, Isai and Grigori. Being residents of Tbilisi, they did not have the initial difficulties of travel permits and hotel registrations; nevertheless, after meeting with newly arrived delegates and talking with them on scientific

Soviet diary

from Vera Rich

topics and also on the difficulties of life as a refusnik, they were called in by the KGB and warned to stay away from the area of the conference building, unless they had had an official invitation from the conference committee. It was not until Saturday, September 6, the penultimate working day of the conference, that Elizaveta Bykova, the wife of Isai and herself a physicist, managed to convey this message to the committee. After a long and forceful meeting between the conference committee and the Georgian hosts, a compromise was reached by which Dr Chavchanidze undertook to invite them for the remainder of the conference on his own personal initiative—a singular example of moral courage.

This reluctance to admit the refusniks seems to be related to the attitude to Israeli scientists. No scientists resident in Israel were allowed to attend, and one Israeli, Dr Y. Yakimovsky, at present working in the USA, received a promise of a visa far too late for him to attend. Nevertheless, two other

Israelis from the USA, Judah Pearl and Meir Weinstein, were permitted to attend, so that the Soviet authorities fulfilled at least the letter of the unofficial working agreement on international conferences—that although individual delegates may be refused entry, no national delegation will be excluded *in toto*.

● The Presidium of the Supreme Soviet of the USSR has announced that "The Order of Friendship of Nations" has been awarded, individually, to each of the Academies of Science of the Union Republics of the USSR, namely, to the Ukrainian, Byelorussian, Uzbek, Kazakh, Georgian, Azeri, Lithuanian, Moldavian, Latvian, Kirgiz, Tadjik, Armenian, Turkmenian, and Estonian Academies, "for service in the development of Soviet science, economics, and culture, and in the training of highly qualified scientific cadres". One Republic only is not so honoured—the Russian Federated Republic, which has no academy of its own.

● Reconstruction work has begun at the highest botanical garden in the world, at Khorog in Tadzhikistan. The garden, at a site in the High Pamirs some 2000 m above sea-level ("above the clouds") is extensively used for field work on the introduction and acclimatisation of plants in extremal conditions. The plants, received on a basis of a regular exchange of seed with 30 Soviet and 36 foreign botanical gardens, therefore include not only and the Hindu Kush, but also more high-altitude flora from the Himalayas plebeian species, including several strains of potatoes, and that mainstay of agricultural planning of the Khrushchev era—maize.

THERE are indications that the new head of the Soviet space establishment, Academician Roald Sagdeyev, has wider interests in space cooperation than costly "spectaculars". Space scientists of the West first made his acquaintance at this summer's COSPAR Symposium in Bulgaria (COSPAR is shorthand for the ICSU Committee for Space Research, the principal international scientific—as opposed to technological—meeting ground). The impression he made was fresh and favourable: he is youngish, full of ideas, and expresses them in excellent English. This is not quite the image projected by his long-surviving predecessor, Academician Blagdonravov—a loveable octogenarian if ever there was one—who died earlier this year.

Sagdeyev's actual post as head of the USSR Institute of Space Research in Moscow puts him in a key position to monitor international developments at

Plans for space

from Angela Croome

least in the physical sciences. Soviet development of ideas for experiments must surely have seemed to stagnate since the 1950s; sputniks were becoming not only relatively smaller but stupider. At the COSPAR meeting, Sagdeyev was not only responsive to the idea of international cooperation in certain fields but showed particular interest in getting involved in X-ray astronomy projects.

On the organisational front, the initiative seems to have passed from the USA (at least temporarily). The formation of the European Space Agency (ESA) as a matching body to NASA has thrown into prominence the lack of a learned body in Europe, comparable with the Space Sciences Board of the US National Academy of Sciences, to give informed but inde-

pendent opinions on the long term objectives of space research. A European Space Sciences Board has now been formed under the formal auspices of the European Science Foundation with Sir Harrie Massey as chairman.

It acts as a clearing house for research ideas in conjunction with the US Academy of Sciences' Board and looks ahead to acting as a joint negotiating body for the West for broad cooperative programmes with the Soviet Union on a range of topics better pursued on a synoptic or systematic basis than from discrete and occasional national spacecraft. The idea of an international space observatory seems particularly to recommend itself to Sagdeyev and his institute colleagues at present. The European Space Sciences Board holds its next meeting—the third—in London in the middle of September, and expects to clarify some of these possibilities. □

correspondence

The WHO and mosquitoes

SIR,—We have read with interest your editorial (July 31) on the allegations made by a section of the Indian press and the Public Accounts Committee of the Indian Parliament against the Delhi-based Research Unit on Genetic Control of Mosquitoes whose activities were jointly implemented and supervised by the World Health Organisation and the Indian Council of Medical Research (ICMR).

With regard to the technical aspects of this controversy, you have highlighted the crucial fact that the authors of the allegations failed to read the abundant literature issued by the research unit, either reports or publications, which were made freely available to them, and that they used logic so tenuous that it does not stand up to unprejudiced examination. We might add that they did not even take the trouble to discuss the controversial points with the many Indian scientists carrying out research at the unit.

We should like, however, to complement your analysis by supplying some additional information on other aspects of the controversy, for which the only documentation that you had was that presented by the authors of the allegations.

Dr Jayaraman's assertion that he was refused information on the project by the WHO because "it was sensitive to the Indian press" does not represent the truth. On the contrary, all co-operation was extended to him and a meeting was immediately arranged under the chairmanship of the Director-General of the ICMR with the Director of the National Institute of Communicable Diseases of India, the unit's Project Leader and Dr Pal of the WHO's Vector Biology and Control Unit at Headquarters. The Chairman invited Dr Jayaraman to raise any questions about the unit's research after he had a chance to see the special issue of the *Journal of Communicable Diseases* devoted to papers on the unit's work. It was most unfortunate that Dr Jayaraman never availed himself of this offer; had he done so, the fallacies in his subsequent published statements might have been avoided. You have also quoted Dr Jayaraman's allegation that he was "indirectly sounded out for a job as an Information Officer at WHO Headquarters", the implication being that this was done in an effort to appease him. No such offer was made

to him; what was offered was the full cooperation of the WHO information services in the preparation of his article. It is noteworthy that Dr Jayaraman did not make this allegation in the press, but only before the Parliamentary Committee.

With reference to the use of chemosterilised mosquitoes, your presentation of the situation is not entirely accurate. The unit's statement that thiotepa residues break down very rapidly in the bodies of mosquitos is not a mere "claim" but is based on investigations, the results of which have been published (LaBrecque, G. C., Bowman, M. C., Patterson, R. S., and Seawright, J. A., *Bull. Wld Hlth Org.*, **47**, 675-676; 1972). The unit's statement that drinking-water wells were never used for the release of chemosterilised pupae is factually correct. Apart from considerations of safety, the use of drinking-water wells (in which *Culex fatigans* does not normally breed) would have defeated the aim of releasing sterile males at the natural breeding sites, which in the area and season concerned are disused irrigation wells. The toxic effects of the well water on laboratory-reared pupae was discovered not because these were released in the wells, but because treated pupae were placed for emergence in this water in containers which in the initial stages were floating and later suspended above the water.

You sharply criticise WHO's handling of public relations during the controversy. We may point out that as an international organisation the WHO does not make any statement which could be construed as intervention in an internal dispute or a matter falling within the domestic jurisdiction of a member state. So long as this was the case, and the question was under investigation by a Parliamentary Committee in India, it was not considered appropriate to publish on this matter.

Finally, your statement that the WHO has "pulled out" may leave a false impression with your readers. The original agreement between the government of India and the WHO establishing the research unit was for a period of six years, which expired on June 30, 1975. The unit developed much essential methodology, carried out several small scale field trials and assisted in the creation of a core group of Indian scientists fully conversant with all the aspects of the research. What is left to be done is to carry out

large scale feasibility studies of new vector control methodology in areas of southern India endemic for mosquito-borne diseases, which does not require the assistance of full-time WHO staff members. It is anticipated that this work will be carried out under Indian leadership now that the WHO has handed over the unit to the Indian Council of Medical Research on the appointed date, with continued WHO technical advice and assistance if requested.

Yours faithfully,

F. J. TOMICHE

World Health Organisation, Geneva

SIR,—Your leader "Oh, New Delhi; Oh, Geneva" (July 31) might as well have been written by the World Health Organisation's Public Relations staff whom you hold responsible for the bad handling of the Indian press that ultimately, according to you, led to the closure of the Research Unit on Genetic Control of Mosquitoes (GCMU) in New Delhi.

The intention of this letter is not to highlight all the crucial omissions you had made (that would make the letter long) but only to correct a few statements which apparently have been taken out of the handout the GCMU had prepared in defence of its project.

You have dismissed the six-volume Stockholm International Peace Research Institute (SIPRI) series on chemical and biological warfare (CBW) in one sentence by saying that SIPRI "has reported that biological warfare (BW) could be conducted with infected mosquitoes."

The SIPRI series in fact says a lot more on entomological warfare. Like genetic control, it is also in the research stage. Our allegation that data gathered by the GCMU on mosquitoes can help BW research is supported by SIPRI which says that ecological data of mosquitos and dispersal data obtained from field trials are useful in BW.

It is well known that only female mosquitoes pick up and transmit viruses. Your categorical statement that GCMU's "work has been exclusively concerned with males" is however, incorrect. The GCMU was to have released at least 2,000 females a day at Sonapat. The male-female sexing error, as claimed by the GCMU, is 0.25% and in practice it may be higher.

Second, dealing predominantly with male mosquitoes need not be a great handicap. A specialist in mosquito ecology can obtain the dispersal pattern of females of a species of mosquito by extrapolating the dispersal data of males.

Your leader gives an erroneous impression that we were the only two "to level accusations of BW." Other witnesses who appeared before the Parliamentary Public Accounts Committee (PAC) belonged to the health and defence ministries. Of course they will not accuse themselves. But if you had carefully read the PAC report you would have noticed statements made by health officials admitting that both the GCMU project and the Jodhpur project (another WHO venture about which your leader is silent) could provide data useful in BW.

You may be "revolted" by the thought that the US government was using an intermediate organisation (WHO) to learn how to infect the Indians with yellow fever. Do you know that the USA was alleged to have used an FAO expert (an Indian) in 1970 to sabotage Cuban sugar cane research?

Do you know that a US expert working at the Indian Agricultural Research Institute (IARI) here was caught at the India-Pakistan border in 1971 with his luggage containing wheat germ plasm collected by the IARI?

It was unfortunate that articles criticising the GCMU and other projects were interpreted to be anti-American. This was never intended. The bird migration studies supported by the GCMU and the US army at the Bombay Natural History Society exemplified the casual attitude of some to foreign funded research. But many other countries have set up collaborative projects covering agriculture, livestock and the continental shelf.

Although we journalists appeared before the PAC late in the day, the same questions put to us were also put to official witnesses and they were given every opportunity to give answers.

You seem to regard the WHO pulling out from an "important" research project as bad. Bad for whom? Not for India which needs to tackle malaria now and not 40 years hence when genetic control may become viable scientifically—but not economically.

As far as filariasis is concerned, an expert report to the Indian Council of Medical Research had clearly said in 1971 that the strategy is not elimination of the vector *Culex fatigans*—but protection with drugs of the vulnerable population below the age

of 21 in the endemic regions.

Chikungunya and dengue are not major health problems in India (as they were made out to be during the GCMU controversy) and control of *Aedes aegypti* has the least priority. That dengue gives cross protection against yellow fever is so strongly established (Theiler, Max, *Arthropod borne diseases in vertebrates*; 1973) that grand projects to eradicate *Aedes aegypti*—even though foreign-financed and with WHO sanction—can be only anything but scientific.

Arguments that yellow fever did not strike after elimination of *Aedes aegypti* from Poona in 1953, are too weak to disprove Max Theiler's conclusion that a person immune to dengue is automatically immune to yellow fever. Such arguments are too childish to be taken seriously by the health department of any country. Yellow fever did not come to Poona perhaps because other vectors of yellow fever were also not present, or there were missing links in the epidemiological chain.

If the closing of the GCMU causes concern to British scientists they may well restart the project around London. It is better that sophisticated technologies (genetic manipulation is one) are first tried and developed in advanced countries before they are recommended to developing countries.

Your worries that India will find few opportunities to collaborate with the rest of the scientific world are unwarranted. Right now India collaborates with some 40 countries. Almost every month some science agreement or other is signed. Under such circumstances it is only natural for the PAC to recommend that foreign research in certain areas like weather modification, and oceanography should be scrutinised from the security angle.

The PAC has not banned foreign collaboration in science but has asked for the closer participation of Indian scientists who are at present given subordinate roles and not decision-making or project-management roles in foreign-funded research. The PAC has also called for thorough scrutiny by a governmental clearing body as you yourself have admitted that "almost everything has its military aspect."

We would like to ask, for instance, if the British government will allow a team of foreign scientists to go about surveying Britain's continental shelf, causing artificial earthquakes in "search of minerals", or releasing new strains of pigeons in Trafalgar Square?

Unwelcome error

SIR,—Something went a little wrong, I am afraid, in the box headed "Wellcome Foundation" in your guide "How Britain Runs its Science" (August 28).

The Wellcome Foundation Limited is the parent company of a British based pharmaceutical group trading as Burroughs Wellcome, Coopers and Calmic around the world. Its chairman is Mr A. A. Gray. Like any other pharmaceutical group it spends money on its own research and development.

All its shares are owned by a registered charity, The Wellcome Trust, which under the Will of Sir Henry Wellcome, who died in 1936, applies all moneys it receives, as sole shareholder, to the support of medical and allied research in universities and hospitals around the world. The Director of The Wellcome Trust is Dr P. O. Williams, and I think it is the Trust rather than the foundation that should have been featured in your guide.

The figure you gave for research grants is actually the foundation's expenditure on research and development for the year ended August 31, 1974.

Yours faithfully,

BASIL SAUNDERS

The Wellcome Foundation Ltd,
London, UK

ED—Indeed the Wellcome Trust, rather than the foundation, ought to have been featured in our guide. Before anyone starts applying for a slice of the £11.5 million which the foundation allocated to research and development last year, we had better point out that the trust's spending on research assistance (1972–74) was £1,133,463.

A hundred years ago

THE German Scientific and Medical Association was opened at Graz on the 17th inst. Lieut. Weyprecht, of the recent Austrian Arctic Expedition, made a speech deprecating all past Arctic expeditions as adventurous and valueless because they constituted an international rivalry that resulted only in giving names to some ice-bound islands. The speaker, amid general applause, expounded a new programme for making Arctic expeditions more fruitful for natural science, and to enable poorer countries to undertake such expeditions from *Nature*, 12, 260; September, 23, 1875

news and views

It has been little more than a year since the first publication (Olins and Olins, *Science*, **183**, 330; 1974) of electron micrographs showing the "string of beads" structure of chromatin. During this period, much other evidence has been presented (*Nature*, **254**, 651; 1975) that, at this lowest level of organisation, the DNA of chromatin is folded together with histones to form morphologically repeating units (called "bodies" or nucleosomes) involving about 190 base pairs of DNA and eight histone molecules each. We still do not know the nature of this folding—the conformation of DNA within the particle, the structure of the histone complexes which constrain the DNA, and whether or not the histone content and DNA conformation of all particles are identical. These questions are examined in several new papers.

DNA folding

Valuable information about DNA folding within the nucleosome has been obtained by chemical methods. A recent paper by Germond *et al.* (*Proc. natn Acad Sci. U.S.A.*, **72**, 1843; 1975) examines the properties of complexes obtained by associating histones with covalently closed circular DNA isolated from simian virus 40 (SV40). Earlier papers (Olins, *J Cell Biol.*, **64**, 528; 1975; Oudet *et al.* *Cell*, **4**, 281; 1975) had shown that the beaded-string structure could be generated by reconstituting DNA with a mixture of each of the four histones H2A, H2B, H3 and H4. By making use of SV40 DNA in the reconstitution experiments, Germond *et al.* are now able to study the effects of nucleosomes on DNA superhelix formation. The experiments depend on the use of an "untwisting extract" isolated from Krebs II ascites cells, which contains an enzymic activity capable of removing the superhelical content of circular covalently closed DNA, leaving a relaxed product that is still a closed circle. Germond *et al.* formed a series of complexes between relaxed circular SV40 DNA and increasing quantities of a mixture of the four histones and treated the complexes with untwisting extract. When DNA was then freed of histone and its superhelical content determined, it was found that superhelix had been generated. The number of negative superhelical turns present in the DNA at the end of the experiment was equal to the number of nucleosomes per molecule observed for the corresponding

String of pearls

from Gary Felsenfeld

nucleoprotein complex in the electron microscope.

These results show that the formation of each nucleosome involves creation of one superhelical turn or its topological equivalent, but do not tell us what the actual DNA conformation is within the nucleosome, since the effect of one negative superhelical turn can also be generated by unwinding the DNA double helix one full turn, or by a series of negative and positive superhelical turns which partially cancel each other. Structural considerations place some limits on speculation, however. A single regular superhelical turn of 120 Å diameter and 110–120 Å pitch will not accommodate the amount of DNA found in the nucleosome but other superhelices can be constructed (Baldwin *et al.*, *Nature*, **253**, 245; 1975). Crick and Klug (*Nature*, **255**, 530; 1975) have proposed a class of models for the nucleosome in which the DNA, rather than being smoothly bent, is kinked at intervals in order to wrap around a core of histones. One specific model that they propose involves a 95–100° kink every 20 base pairs, generating between two and three left-handed superhelical turns in 190 base pairs. This model appears to be outside the range suggested by the results of Germond *et al.*, but it is easy to imagine variations of the model which would fit better, since the sense and pitch of the kinked supercoil are sensitive to the number of base pairs between kinks.

There is some question also about what fraction of the 190 base pair repeating DNA subunit is actually in the "bead", and what fraction is in the "string". Several investigators (Van Holde *et al.*, *Biochem. biophys. Res. Commun.*, **60**, 1365; 1974; Solner-Webb and Felsenfeld, *Biochemistry*, **14**, 2915; 1975; Axel, *Biochemistry*, **14**, 2921; 1975) interpret the electron microscopic and nuclease digestion results as indicating the presence of a string occupying perhaps 50 base pairs of the subunit. This part of the DNA, seen in the microscope as a fibre 15–20 Å in diameter, is probably not supercoiled, though it could be thinly covered by a

histone chain, perhaps wound in one of the grooves of the double helix. Noll *et al.* (*Science*, **187**, 1203; 1975) however, take the position that all of the DNA in native chromatin is wound into the nucleosome, and that the strings between nucleosomes are seen only if chromatin is subject to disruptive shearing forces. The electron microscopic studies of Griffith (*Science*, **187**, 1202; 1975) on naturally occurring SV40 DNA–histone complexes indicate that the string regions are visible at low ionic strength, but disappear from view as salt concentration is raised to 0.15 M, suggesting that these regions are in some way a unique part of the unit structure.

Arrangement of histones

The other half of the nucleosome structure problem has to do with the arrangement of the histones. The known histone content of chromatin is approximately consistent (Kornberg, *Science*, **184**, 868; 1975) with a repeating unit containing eight histones (two each of H2A, H2B, H3 and H4) for each DNA repeat of 190 base pairs. An (H3H4)₂ tetramer is present in histone fractions prepared by salt dissociation of chromatin (Kornberg, *loc. cit.* Kornberg and Thomas, *Science*, **184**, 865; 1974). Kornberg proposed that the chromatin structure was built upon a core of this tetramer, to which were added two H2A–H2B dimers to complete the octameric structure. Since histones H3 and H4 spontaneously form dimers and tetramers in solution (Roark *et al.*, *Biochem. biophys. Res. Commun.*, **59**, 542; 1974; D'Anna and Isenberg, *Biochemistry*, **13**, 4992; 1974) the presence of such complexes after release from DNA does not constitute conclusive proof of their arrangement within the chromatin structure. A more satisfactory approach to the problem is to treat chromatin with protein crosslinking reagents, and identify the histone oligomers which result, a method that has proved valuable in the study of other nucleoprotein complexes. Martinson and McCarthy (*Biochemistry*, **14**, 1073; 1975) have used tetranitromethane to demonstrate the presence of an H2B–H4 dimer in chromatin; they find that this dimer also forms when histones are reconstituted with DNA, but only when H2A is also present. VanLente *et al.* (*Cell*, **5**, 45; 1975) have treated nuclei and chromatin with formaldehyde, producing dimers of H2B with H4, and H2A with

H2B, while Bonner and Pollard (*Biochem. biophys. Res. Commun.*, **64**, 282; 1975) have generated an H3-H4 dimer using carbodiimide. Thomas and Kornberg (*Proc. natn. Acad. Sci. U.S.A.*, **72**, 2626; 1975) are the first to report the isolation of cross-linked histone octamers. Chromatin is treated with dimethyl suberimidate (Me_2Sub) or dithiobis (succinimidyl propionate) (Lomant's reagent). At pH 9, reaction with Me_2Sub produces a series of protein oligomers ranging in molecular weight from dimer to octamer, but there is little or no oligomer of larger size. Using Lomant's reagent, the principal low molecular weight product is octamer, but higher molecular weight products (16-mer and higher) also occur. It is not yet determined whether the octamer represents a single species or a mixture of several complexes varying in histone content, but of about the same molecular weight. Examination of the dimers produced as reaction intermediates by Me_2Sub has led to identification of $(\text{H3})_2$, H3-H4, H2B-H4, H2A-H4, and probably H2A-H2B. The same pairs were obtained when chromatin monomers (isolated single nucleosomes) were crosslinked, suggesting that these pairs are representative of short-range interactions within the monomer.

Are all nucleosomes identical in histone content and arrangement? That

is the simplest and most reasonable working hypothesis, but it remains to be demonstrated. If there is some variation in the histone content of nucleosomes, it must be subject to certain rules of substitution, since nucleosomes seem to be fairly homogeneous in protein mass, and there is some variation among histones in molecular weight. If the nucleosomes are all identical in histone content, it is still possible that variations in internal folding or arrangement exist. This is an unattractive hypothesis because multimeric protein complexes tend to have unique arrangements. On the other hand, naturally occurring histone modifications such as phosphorylation are known to have a major effect on physical properties that might affect the way histones fold or interact.

An attempt to probe the internal arrangement of histones has been made by Weintraub (*Proc. natn. Acad. Sci. U.S.A.*, **72**, 1212; 1975) who has examined the products obtained when chromatin is digested extensively with staphylococcal nuclease, and then with trypsin. The trypsin digestion removes only 20 to 30 amino acid residues from the histone N-terminals; when the resulting nucleoprotein fragments are examined by electrophoresis on acrylamide gels, eight discrete nucleoprotein bands are observed. Four of these can be shown to carry C-terminal

portions of histones H2A, H2B, H3 and H4, one carries only H3 and H4 C-terminals, and three bands are altogether free of protein, presumably because they carried the trypsin-sensitive N-terminals. If chromatin is digested first with trypsin and then with nuclease, results consistent with this hypothesis are obtained: the protein-free bands generated by nuclease-trypsin treatment are not present in the trypsin-nuclease digest because the N-terminal attachments which protect these bands against nuclease attack have been destroyed. Weintraub's results reflect a well-defined architecture of histone-DNA attachment sites within the nucleosome. But the number and size of the fragments is too large to have arisen from a single kind of nucleosome particle undergoing degradation along a single pathway. It is possible that there are several paths of degradation leading from the same starting point to different sets of products, so that the appearance of multiple fragments in the digest cannot be taken as unequivocal evidence for heterogeneity of nucleosomes. Proof that there is only one kind of nucleosome, however, also awaits definitive quantitative experiments. If nucleosomes are homogeneous, the hope exists that they can be crystallised, and their structure determined by the direct methods of X-ray diffraction. □

YET another satellite of Jupiter has been discovered, the thirteenth. Unlike new comets and asteroids, which seem to pop up at frequent intervals, new satellites are much less common, Jupiter XII being found in 1951 and Saturn X in 1966. Needless to say planetary discoveries are rarer still, coming at a rate of about one every 75 years (Uranus 1781, Neptune 1846 and Pluto 1930).

The discovery, observations and attempts to determine the orbit of Jupiter XIII are discussed in a recent paper by four American astronomers Kowal, Aksnes, Marsden and Roemer (*Astr. J.*, **80**, 460; 1975). They used the 122-cm Schmidt telescope at Palomar Mountain and on three consecutive nights during September 1974 photographed a $6^\circ \times 6^\circ$ field centred on Jupiter. The plates were exposed for 120 min, the telescope being guided to follow Jupiter. At the time Jupiter was near opposition (at its closest to Earth, about 3.98 AU away) and of magnitude -2.5 . The authors estimated that the faintest images that could be detected on each plate, for an object sharing Jupiter's motion, were of magnitude about $+0.22$, equivalent to a brightness 6×10^9 times less than Jupiter's.

The satellite was discovered during

the course of 'blinking' the plates—a process in which two plates are looked at in quick succession and any image which has moved relative to the fixed background stars appears to jump to and fro as each plate is successively observed. Accurate measurements of the first three plates showed that the object's motion during September 11–13 could lie on two possible orbits, a direct joviocentric one and a heliocentric orbit similar to that of an asteroid. This confusion was only resolved after seven more plates were taken, the latest on December 12 when Jupiter was more than three

Jupiter XIII

from David W. Hughes

months past opposition and at a distance of 5.03 AU. Four of these were obtained using an image tube attached to the Steward Observatory's 229-cm reflector on Kitt Peak, the plates requiring only 1.5 min exposures.

Just considering their distances from Jupiter, the Jovian satellites seem to fall into three distinct groups, (I-V), (VI, VII and X) and VIII, IX, XI and XII, these being within 1.8, around 12 and between 21 and 24 million km from the planet with wide

empty gaps in between. The new satellite XIII is a member of the second group having an orbit with semi-major axis 0.074 AU (11.1 million km), eccentricity 0.147, inclination 26.7° and period 239 d. Its photographic mean magnitude is close to 21, about 1.5 magnitudes fainter than Jupiter XII. The radius of Jupiter XII is estimated to be around 8 km so Jupiter XIII is probably smaller. Whether these outer satellites are true-born children of Jupiter, formed in the same epoch, or whether they have been adopted at some later date remains as yet uncertain. Jupiter's seven outer satellites all have radii less than 12 km and could easily be captured asteroids probably with shapes and surface features like Phobos and Deimos, the moons of Mars.

Interestingly, Kowal *et al.* state that for the next few years there is about an even chance that each annual Jovian opposition could see the discovery of a new satellite, of comparable brightness to Jupiter XIII. The satellite would however have to be near its extreme elongation east or west of Jupiter. The opposition in 1975 (around October 13) is especially favourable as Jupiter is at the perihelion of its orbit and only 3.96 AU from the Sun.

From nuclear β decay to the charges of quarks

from R. J. Blin-Stoyle

ELEMENTARY particle or high energy physics became established as a subject in its own right during the immediate postwar years and its varied and often surprising revelations about the fundamental structure of matter have continued unabated since then. It developed from research into the properties of atomic nuclei; but whereas most nuclear properties can be unravelled using low energy (tens of MeV) accelerators and many body theory, the creation of new particles and the study of their properties requires vastly higher energies (tens of thousands of MeV and more) and has led to the development of most elegant but continually evolving theories. Nevertheless, low energy nuclear physics continues to make important contributions to our understanding of the physics of elementary particles. This brief commentary is intended to illustrate the foregoing by taking as an example some recent deductions of Wilkinson (published in this issue of *Nature*, page 189) based on very careful measurements of nuclear β -decay rates and energies.

Quark-parton model

To set the scene it must first be stated that research in high energy physics has led to the discovery of many hundreds of elementary particles and to the elucidation of their interactions and properties. In particular it has become clear that their behaviour is conditioned by three basic interactions which, in descending order of strength are known as strong, electromagnetic and weak. The strong interaction is responsible, for example, for the powerful forces that hold the nucleus together; the electromagnetic interaction is well known and manifests itself in all electromagnetic phenomena; the weak interaction is responsible, among other things, for the radioactive decay of elementary particles and, in particular, for the process of nuclear β decay. But the main properties of particles are naturally determined by the dominating strong interaction and at the present time it seems likely that the nature of the strong interaction is such that particles which experience it, and this includes the vast majority, are all, in some sense, composite structures of a very small set of basic particles (or their anti-particles) called quarks. For example, the component particles of the nucleus, namely neutrons and protons, are regarded as consisting of three quarks which, incidentally, may further be identified with the point-like objects known as partons indicated by some

experiments to be constituents of elementary particles.

What Wilkinson has done is to assume the correctness of the quark-parton model and then to derive the charge of these constituent particles from β -decay data. This is a remarkable connection to make and inevitably intermediary assumptions and hypotheses have to be made in achieving it. But what is important is not so much the result and the extent to which it can be considered reliable, but the fact that the connection can be made and can clearly be improved and developed in the future.

Briefly the steps taken are as follows. They start naturally from basic input experimental data—the lifetimes and energy release of certain particularly simple nuclear β decays known as superallowed transitions. The measurements involved which, it must be stressed, have been carried out to extremely high accuracy, have been the preoccupation of Joan Freeman and her colleagues at Harwell over the last decade or so and more recently by other researchers in Canada and the USA. From these data it is then possible to deduce the strength of the β -decay interaction. Fortunately the deduction is very largely independent of the nuclear structure details for the decays concerned—indeed, this is why they were chosen for study. The strength is measured by a coupling constant $g_{\beta V}$ (where V signifies that we are dealing with the vector part of the β -decay interaction), which has a similar role to the proton charge e characterising the strength of the electromagnetic interaction. In fact, the similarity is more than trivial and in deducing the value of $g_{\beta V}$ it is assumed that the weak ‘current’ responsible for the superallowed β decays is conserved (the well established conserved vector current hypothesis) in analogy to the electromagnetic current. The only difference is that it is a charged current and causes the decaying nucleus to change its charge when it decays (since it emits an electron or positron) whereas the electromagnetic current is neutral so that a nucleus decaying electromagnetically retains its charge (since it emits a photon).

Cabibbo universality

Now it is a further hypothesis of weak interaction physics that it is universal in the sense that all weak interaction processes are governed by essentially the same coupling constant g to which $g_{\beta V}$ must therefore be related. The hypothesised relation is simple, namely, $g_{\beta V} = g \cos \theta_c$ where

θ_c is known as the Cabibbo angle. Here it should be remarked that nuclear β decay conserves ‘hypercharge’, a quantity rather analogous to ordinary electric charge, but that in those decays of elementary particles which do not conserve it the relevant coupling constant is $g \sin \theta_c$. Thus, this ‘Cabibbo universality’ simply involves the sharing of the strength g between these two different categories of β decay. The value of θ_c can be determined with quite reasonable accuracy from data on hypercharge non-conserving β decays and so, using the expression $g_{\beta V} = g \cos \theta_c$ and knowing $g_{\beta V}$ and θ_c , the value of g can be obtained.

However, assuming the universality of the weak interaction already referred to, g is also the coupling constant governing the decay rate of the μ -meson into an electron, neutrino and antineutrino. This decay is unique and simple to treat theoretically since, in contradistinction to the β -decay situation, none of the particles involved experience strong interactions. In addition its rate has been measured accurately so that a value for g can be obtained very straightforwardly. However, before comparing the values of g from β - and μ -decay data, corrections due to electromagnetic effects have to be made to both values. These are known as electromagnetic radiative corrections and result from the modification of the decay rates due to the electromagnetic interactions between the particles involved in the decays. The difference in these corrections for the two decays, and this is all that concerns us here, is related to two quantities. First, being an electromagnetic effect, the β -decay radiative correction naturally depends on the charges of the constituent quarks of the neutrons and protons involved in the decay. Second, for both β - and μ -decay the correction depends on a characteristic mass M , and here we come to the final hypothesis to be introduced.

Over the last few years theories have been developed which unify the weak and electromagnetic interactions. One particularly successful version is that of Salam and Weinberg and is well supported by recent neutrino scattering experiments which establish the presence of neutral weak currents (as distinct from the charged currents already mentioned). Just as the neutral electromagnetic current couples to the photon, so the neutral weak current couples to a very heavy uncharged (that is, neutral) meson whose mass can be determined from the neutrino

scattering experiments. Assuming the validity of the Salam-Weinberg theory it then transpires that the mass M arising in the β - and μ -decay electromagnetic radiative corrections is just that of the neutral meson.

The connection is now complete and all that remains is to choose the quark charges so that the values of g derived independently from the β - and μ -decay data agree with one another. Suffice it to say that Wilkinson's results are consistent with one third integral charges for quarks as originally suggested by Gell-Mann and Ne'eman and not with integral charges as suggested recently.

As stressed earlier in this commentary the result, although extremely interesting in itself, does rest on a rather complex edifice of hypotheses

and theories some components of which are perhaps a little delicate. What is important is that it has been shown how quite fundamental information about properties of elementary particles can be derived from very accurate measurements within the framework of conventional low energy physics. There are other properties of elementary particles and their interactions that are being studied in similar ways (such as time reversal invariance, parity violating nuclear forces, exotic interactions) and there are those of us who feel that, quite apart from achieving a full understanding of the nucleus as a many-body system, there are these other important reasons for continuing detailed studies of nuclear phenomena. \square

F_c receptors and Ia antigens: a postscript

from Robert S. Kerbel

Is there a unique relationship between Ia antigens and F_c receptors on the surface of B lymphocytes? As discussed in a recent *News and Views* article (*Nature*, **255**, 576; 1975), an affirmative answer to this question would almost certainly have far-reaching implications for various aspects of the immune response and its regulation: these have been succinctly summarised (*Transplant Rev.*, **23**, 159; 1975) by the same investigators who in fact first presented evidence for an identity or close association between F_c receptors and Ia antigens on B cells (Dickler and Sachs, *J. exp. Med.*, **140**, 779; 1974).

To summarise briefly: Ia antigens are a system of alloantigens controlled by the I (immune response) region of the major histocompatibility gene complex (H-2) in the mouse. They are expressed in quantitatively significant amounts on B cells, and appear to be responsible for, among other things, the generation of mixed lymphocyte responses in culture and the generation of *in vivo* graft-versus-host responses. The F_c receptor is a cell-surface component which interacts with the F_c portion of certain immunoglobulins and is found on a wide variety of cells, including B lymphocytes. It has potential significance in a spectrum of immunological phenomena. Dickler and Sachs suggested that a special relationship may exist between Ia antigens and F_c receptors on the basis of experiments in which the binding of aggregated immunoglobulin (Ig) to B cell F_c receptors was inhibited by anti-Ia antibodies but not by anti-H2K, anti-H2D, or anti-Ig antibodies.

Schirmmacher *et al.* (*J. exp. Med.*, **141**, 1201; 1975) however, found no evidence for a unique association, on

the basis of results obtained from two alternative assays both of which utilised the same basic idea of assessing the relationship of cell surface components to F_c receptors by the ability of antibody (against these components) to inhibit F_c receptor binding. As was pointed out, these results, although they provided no support for a unique association theory, did not formally disprove the notion either. More direct evidence is needed to settle this controversy: in this issue of *Nature*, Rask, Klareskog, Ostberg and Peterson (page 231) have tried to provide such evidence by isolating B cell F_c receptors and examining some of their properties. Their results appear to show that neither an identity nor close association exists between F_c receptors and Ia antigens.

Rask *et al.* prepared soluble macromolecules from crude membrane fractions of mouse spleen cells which were then subjected to affinity chromatography on a column of sepharose beads to which heat-aggregated IgG molecules had been covalently attached. Any soluble F_c receptors would be expected to bind to the aggregated Ig which could then be eluted. When such eluted material was subjected to polyacrylamide gel electrophoresis, Rask *et al.* found three types of sialic-acid containing polypeptide chains with apparent molecular weights of about 65,000, 18,000, and 15,000. Evidence was cited by the authors which indicated the three components behaved like F_c receptors in that they had affinity for soluble immune complexes.

The remainder of the experiments involved the use of rabbit antisera raised separately against the 65,000 dalton material and the mixture of the 18,000 and 15,000 dalton components.

When these antisera were incubated with mouse lymphoid cells they appeared to react only with B cells which would be expected if the antibodies had specificity for F_c receptors. IgG and $F_{(ab')_2}$ fractions of these antisera also possessed the ability to inhibit the uptake of aggregated human IgG on to B cells.

The authors then examined the possibility of a close relationship existing between Ia antigens and F_c receptors by use of the so-called 'lysostripping' method, which is based on the assumption that independent molecules float freely in the cell membrane, and can be redistributed by antibodies into 'caps' on the cell from an originally diffuse or patchy distribution. The cells then become specifically resistant to complement-dependent lysis when further incubated with antibodies directed against the capped antigens. Antibodies against other cell surface components however retain their full cytotoxic ability provided an intimate relationship does not exist between them and the capped antigens. If such a relationship does exist, these other surface components can be 'co-capped' as well, resulting in resistance to complement-dependent lysis. The principle of co-capping of cell-surface components was one of the first methods used, for example, to show that a close physical relationship exists between histocompatibility antigens and β -2 microglobulin (Poulik *et al.*, *Science*, **182**, 1352; 1973).

When Rask *et al.* incubated spleen B cells with their presumptive anti- F_c receptor antisera so as to induce capping, the cells subsequently became resistant to lysis mediated by the same antisera; but when tested with anti-Ia sera, the cells were apparently killed, that is the Ia antigens did not appear to co-cap with the F_c receptors. The authors conclude that no unique association exists between Ia antigens and F_c receptors although they may lie adjacent to one another in the cell membrane.

An attempt to help resolve another controversy surrounding Ia antigens; their presence or absence on T cells, also appears in this issue of *Nature* (page 230) by Goding, White and Marchalonis. Previous reports have indicated the presence of Ia antigens only on B cells, or on both B and T cells. The reasons for the discrepancies are unclear but may be partially due to the nature and potency of the anti-Ia sera used in various studies. In any case, Goding *et al.* demonstrate the specific immunological precipitation of small amounts of Ia antigens from extracts of surface radioiodinated thymocytes using an anti-Ia serum of very high titre. The results are consistent with recent serological data showing the

presence of very small amounts of Ia antigens on less than 50% of thymocytes, a finding made possible by the use of a fluorescence-activated electronic cell sorter (Fathman *et al.*, *J. Immun.*, **115**, 584; 1975). More conventional procedures such as immunofluorescence, cytotoxicity, and absorption of antisera, do not allow detection of Ia antigens on thymocytes although they readily do so on B cells.

The presence of small amounts of Ia antigens on thymocytes is more than vaguely similar to the story of Ig on thymocytes and T cells. Since it seems that the presence of Ig on T cells is sometimes a result of its passive adsorption on to the surfaces of the cells, and not to its endogenous synthesis, an obvious point arises as to whether the same is true for Ia antigens and thymocytes. Indeed, it has been demonstrated by Vitetta *et al.* (*J. Immunogenet.*, **1**, 82; 1974) that, in contrast to H2 antigens, soluble Ia antigens are readily shed into incubation medium containing Ia-positive lymphocytes. In addition, passage of Ia-positive lymphocytes down a column of nylon wool (a procedure used to deplete cell populations of B cells) seems to remove selectively some of the Ia antigens from the surface of the B cells (Schultz *et al.*, *Cell. Immun.*, **16**, 125; 1975, and Fathman *et al.*, *J. Immun.*, **115**, 584; 1975).

These intriguing findings, besides being of some significance themselves with respect to Ia antigen function, will no doubt ensure perpetuation of the controversy surrounding the presence and relationship of Ia antigens to T cells. □

More new particles

In the article 'More new particles' which appeared in News and Views last week an editorial change implied that a section was a full account of work discussed at the recent Lepton-Photon conference at Stanford; the article was in fact received before the Stanford conference.

Nuclear states of high spin

from P. E. Hodgson

ONE of the most powerful ways of determining the spins of nuclear states is by one-nucleon transfer reactions: the angular distribution of the emitted particles is characteristic of the angular momentum transfer, and this usually suffices, sometimes in association with other data, to fix the spin of the final state in the residual nucleus.

This method works best for low

spins, corresponding to angular momentum transfers of 0, 1 and 2. For higher spins the angular distribution is not so characteristic, and the reaction may be forbidden by the spin selection rules.

Among the methods applicable to high spin states the ($^7\text{Li}, p$) reaction is proving useful, and a recent paper by Bishop and Fortune (*Phys. Rev. Lett.*, **34**, 1350; 1975) provides a good illustration of this.

At low energies on light nuclei the ($^7\text{Li}, p$) reaction proceeds predominantly through the compound nucleus. The ^7Li is captured by the target nucleus to form a compound system which then can decay by proton emission. It is then found that the total cross section for the reaction is closely proportional to $(2J+1)$, where J is the spin of the final nuclear state. This relation has been tested for a large number of states, and can be used with some confidence to determine unknown spins.

Total cross sections for the $^{14}\text{N}(^7\text{Li}, p)^{20}\text{F}$ reaction to a number of positive and negative parity states of ^{20}F plotted as a function of $(2J+1)$.

Bishop and Fortune studied the reaction $^{14}\text{N}(^7\text{Li}, p)^{20}\text{F}$, and their results for some positive and negative parity states of ^{20}F with known spins are shown in the figure. The cross sections are closely proportional to $(2J+1)$ and the ratio of the total cross section to $(2J+1)$ is 5.05 ± 0.08 for the positive parity states and 6.74 ± 0.20 for the negative parity states. The proportionality is so closely followed that it is possible to use the total cross sections for the ($^7\text{Li}, p$) reaction to determine the spins of some other states. The identification can be strengthened by seeing how well the state fits into the rotational band structure of the low-lying states of ^{20}F .

The method used is simply to calculate the spin from the expression $\frac{1}{2}[(\sigma_T/5.05)-1]$ for positive parity states and $\frac{1}{2}[(\sigma_T/6.74)-1]$ for negative parity

states and to compare these spin values with those of the possible states that fit into the band structure.

For the state at 2.87 MeV for example, the calculated spins are 3.5 for a positive parity state and 2.5 for negative parity. For the known band structure the assignment 3^- is considered the most likely. In a similar way one of two states at 2.97 MeV is probably identified as 4^- . Probable spin assignments are made to several other states as well.

This work shows the usefulness of the ($^7\text{Li}, p$) reaction in determining the spins of nuclear states, when used in conjunction with other techniques. □

Bird song dialects

from John R. Krebs

SONG birds, like humans, have local dialects. Regional variations in the form of territorial song have been found in such birds as chaffinches, tree-creeper, cardinals, white-crowned sparrows and song sparrows. Often dialect regions are quite small, in the order of a few miles across, and the transition between them may be very sudden. Within a dialect region all males have similar songs whereas between regions the song varies considerably. Playback experiments in which recorded songs are broadcast inside a territory have shown that males can tell the difference between songs of their own dialect and those from other regions (Lemon, *Anim. Behav.*, **15**, 538-595; 1967; Milligan and Verner, *Condor*, **73**, 208-213; 1971); territorial males react more vigorously to songs of their own dialect region.

Dialects probably originate as a result of young birds learning the songs of nearby adults soon after leaving the nest. In the white-crowned sparrow, for example, young males learn the territorial song within the first three months after leaving the nest, so that they are likely to learn the characteristic song of their birthplace.

Several workers have suggested that dialects play a role in the genetic adaptation of populations to local environmental conditions, by acting as a reproductive barrier between populations. This is based on the assumption, as yet untested, that females as well as males can recognise songs of their own dialect region, and will mate preferentially with local birds. Nottebohm (*Condor*, **71**, 299-315; 1969) found that dialect boundaries in a South American sparrow, the chingolo, correspond with changes in habitat structure, for example from grassland to forest, which is what one would expect if dialect regions represented locally

adapted populations. The most obvious prediction of this hypothesis is that dialect boundaries should coincide with genetic boundaries between populations, and this has recently been tested by Baker (*Evolution*, **29**, 226-241; 1975). Baker, working with white-crowned sparrows, used electrophoretic techniques to examine the differences between local populations in the frequency of marker genes, in the Colorado Rockies and at Point Reyes, California. The study area in California was apparently uniform open scrubland, but nevertheless there were sharp dialect boundaries associated with minor habitat features such as an old fence or a ditch. Baker examined the changes in allele frequency across one dialect boundary, and the overall picture for six loci was of quite marked changes at the boundary, with little change within either dialect region. This result seems to support the reproductive isolation hypothesis, but if the populations are adapted to local conditions, the adaptations must be rather subtle since the habitat did not obviously change at the boundary.

In the East River valley system in Colorado, Baker found that all the birds sang the same dialect, but there were changes in allele frequency at three loci associated with changes in altitude. So genetic subdivision of populations can occur without division into dialect regions. Taken together, Baker's results do not provide convincing support for the role of dialects in reproductive separation of populations, and he suggests that whether or not dialect and genetic boundaries coincide may depend on how an area is colonised. The Californian scrub habitat is occasionally devastated by fire, so that the white-crowned sparrow population is reduced to a few birds living in isolated patches of surviving scrub. Dialect regions probably arise through the subsequent spreading of these isolated groups as the habitat recovers, slight differences in song between the founder members of each group being perpetuated by cultural transmission, and slight genetic differences arising by chance. The Colorado valleys are stable and the population of sparrows does not get separated into isolated groups, hence dialect regions have not been established. Presumably genetic changes have arisen through selection in the face of gene flow.

The next step in following up Baker's study will be to find cases (for example small islands) where the colonisation and establishment of dialect differences can be tracked in detail. It remains to be seen whether or not a clearer link between genetic and dialect subdivisions will be found in species like the chingolo where dialects are associated with habitats. □

Genetic arrangement in eukaryotic DNA

from T. H. Rabbitts

THE 'amount' of DNA in eukaryotic genomes is known to be extremely large. The mammalian genome, for example, consists of around 5×10^9 base pairs (per haploid set) which would be sufficient to code for about two million proteins each containing 650 amino acids. In addition it is known that eukaryotic DNA consists of both single copy sequences and repetitive sequences (sequences present as multiple copies in the genome). Two questions currently receiving critical appraisal are how the different types of DNA sequences are arranged in the genome and how much of the genome actually carries protein coding information.

Much evidence has been accumulating in support of the general concept that in many eukaryotes a large percentage of the middle repetitive DNA (DNA sequences present in a few hundred copies per haploid genome) is interspersed amongst single-copy sequences. These single copy sequences are typically about 1,500 nucleotides long with the repetitive elements being around 300 nucleotides long. In two recent papers, Britten, Davidson and their co-workers have extended this evidence and produced a general review of DNA sequence organisation of eukaryotes. In the study by Goldberg *et al.* (*Chromosoma*, **51**, 225; 1975) the sequence arrangement of five marine invertebrates was determined by the examination of the reassociation kinetics of two different length DNA fragments (300 and 3,000 bases). Hybrid formation was assayed by hydroxyapatite fractionation so that DNA fragments carrying a repetitive sequence plus a non-repetitive sequence would kinetically appear in the repetitive part of the DNA reassociation curve. Using this method, all the genomes studied were found to possess a large portion of their single copy sequences interspersed with repeating sequences. In addition it was shown that these repetitive sequences are about 300 bases long.

Davidson *et al.* (*Chromosoma*, **51**, 253, 1975) have correlated the data on sequence organisation in a wide variety of metazoa. They conclude that the DNA of organisms from most branches of the evolutionary tree shares the property of containing both unique and repetitive sequences in at least 70% of DNA fragments 2,000 to 3,000 bases long. The only exception (for which data are available at present) seems to

be *Drosophila* DNA. A study of this DNA has been made by Manning *et al.* (*Cell* **4**, 141; 1975). These workers examined the interspersion pattern of single copy and repeating sequences using both the hydroxyapatite procedures and electron microscopy of re-associated fragments of differing length. It was observed that *Drosophila* DNA has an average distance of around 13,000 nucleotides between middle repetitive sequences. This number of bases is on average about six times as great as that found in the organisms reviewed by Davidson *et al.* In addition to the data of Manning *et al.*, randomly chosen fragments of *Drosophila* DNA have been cloned in *E. coli* and the re-association properties studied (Wensink *et al.*, *Cell*, **3**, 315; 1974; Glover *et al.*, *Cell*, **5**, 149; 1975). So far, the cloned DNA chosen for study has revealed only segments of DNA lacking internal repetition over as many as 15,000 to 27,000 bases. These data seem to prove that *Drosophila* DNA does not possess short repeating sequences interspersed with single-copy DNA. Further examples of the '*Drosophila*' type organisation may well soon be discovered.

Whether the interspersing nature of repetitive sequences in organisms such as *Xenopus* has any direct relevance to gene control is far from clear. Indeed, there are indications that not all repeating DNAs possess regulatory function since cytoplasmic messenger RNA-like molecules have been shown to hybridise to repetitive sequences in a variety of organisms. This leads to the question of how much of the genome actually carries protein coding information. Hybridisation kinetic analysis has recently been used to examine this problem quantitatively. Bishop *et al.* (*Nature*, **250**, 199-204; 1974) prepared complementary DNA (cDNA) against poly(A)-containing RNA of HeLa cell cytoplasm using reverse transcriptase. The kinetic complexity of the RNA population was then determined by hybridisation of excess RNA with cDNA. Using this method, Bishop *et al.* concluded that HeLa cell cytoplasm contains as many as 35,000 different mRNA species. This number of gene products is much higher than the number obtained from a similar study of *Drosophila* referred to by Izquierdo and Bishop and described in detail by Levy and McCarthy (*Biochemistry*, **14**, 2440; 1975). In the latter cases, an mRNA complexity around 4,000 to 7,000 species was found. These numbers compare nicely with the number of bands seen by Bridges in polytene chromosomes (*J. Hered.*, **29**, 11; 1938). What then is the function of the excess DNA which makes up the genome?

Excluding the genes for the rRNAs and tRNAs it begins to look as if a much greater complexity of nuclear

RNA exists than is found for cytoplasmic RNA. Hough *et al.* (*Cell*, **5**, 291; 1975) have studied the hybridisation of purified radioactive unique sea urchin DNA in RNA-excess reactions with gastrula nuclear RNA. These experiments indicate that around 28% of the total complexity of the sea urchin genome is represented in this nuclear RNA. This complexity of nuclear RNA is at least an order of magnitude higher than that found for sea urchin polysomal mRNA. Earlier experiments (Getz *et al.*, *Cell*, **4**, 121; 1975) with mouse Friend cells arrived at similar general conclusions. In this work, the complexity of poly(A)-containing nuclear RNA was assessed by kinetic hybridisations with cDNA. The authors conclude that at least five times more unique DNA is represented in the nuclear RNA than in the polysomal mRNA of these cells. Although the numbers involved in the papers of Hough *et al.* and Getz *et al.* are somewhat different (this difference probably being a result of the use of total nuclear RNA in the former case and poly(A)-containing nuclear RNA in the latter case), the general conclusion is the same—a larger amount of the genomic information is synthesised into nuclear RNA than is present in the cytoplasmic poly(A)-containing RNA. This disparity between the two RNA populations allows speculation regarding the function of the RNA which seems to remain in the nucleus.

Even with these detailed numerical analyses of eukaryotic gene complexity, very little is known of the fine structure of individual genes and genetic units. Studies of these structures should clarify the nature of the controlling elements and specific informational organisation in eukaryotic DNA. □

Excited atoms

from a Correspondent

The ninth international conference on "The Physics of Electronic and Atomic Collisions" was held in Seattle on July 24–30.

ATOMIC physics is finding applications in horticulture: Sir Harrie Massey, delivering the opening scientific talk of the conference, reminded delegates that the study of negative ions, in what was non-applied research in atomic physics, resulted in the method for determining levels of DDT in crops. Though that particular spin-off was successful the nuclear fusion story is a less cheerful one: the level of aid so far given to the thermonuclear fusion programme is worrying. Delegates at

the conference were aware of the immediate need for atomic scattering cross-section data to assist in the construction of a viable fusion machine. It was stressed that measured cross sections for electron scattering of highly excited and ionised atoms and molecules was needed immediately to enable a composite picture of the competing processes in the 'fusion plasma' to be made. An estimated 40% of the power losses from the injected ion beams occurs through the presence of impurity ions such as C^+ , Fe^+ , Mo^+ by way of electron capture, dielectronic recombination and bremsstrahlung losses. But the problem, as expressed by some delegates, is that "the cross section we want today isn't the one we need tomorrow".

Experimental investigations into highly excited states of atoms, for example H, Na, Xe, has advanced very rapidly since the last meeting. In addition to using charge exchange methods for producing high rydberg states, one group (R. F. Stebbings *et al.*, Rice University, Houston) reported that they had used tunable dye lasers in selecting individual high rydberg states in Xe and then measured the ionisation cross section in SF_6 . The use of these highly excited atoms in scattering experiments is now within the range of existing experimental techniques.

Lasers have not yet been exploited to the full in atomic physics for state selection. State and velocity selection of neutral atoms by photo-detachment of the negative ion (C. Linberger, GILA, Boulder, Colorado) is sure to advance the field of reactive scattering. Several groups are considering the determination of atomic beam composition by selective laser pumping.

Doppler free spectroscopy has advanced rapidly; fine and hyperfine transitions can now be measured more easily and accurately than before. The excitation of the $H(1S) \rightarrow H(2S)$ transition by two 2,341 Å photons, using the $H\beta$ level as a reference, has enabled the Lamb shift of $H(1S)$ to be measured. Multiphoton processes and level shifts using lasers are being extensively investigated in many laboratories in the USA and Europe.

The excellent electron scattering work done by many groups has now been complemented by positron scattering data. The measurement of positron differential scattering cross sections awaits the development of higher intensity sources.

The conference indicated very strongly the need now for experimental data on excited state phenomena, not only to aid applied research, but in order to understand better the nature of continuum interactions (U. Fano, University of Chicago) and the formation of bounding molecular states. □

Progress in binary circles

from John Faulkner

At three-year intervals since 1969, the International Astronomical Union has sponsored meetings to review some aspect of our knowledge of close binary stars. The latest and by general consent most successful meeting took place in and around the newly designated Hoyle building at the Cambridge Institute of Astronomy on July 28–August 1. Attendance has more than doubled at successive meetings; IAU Symposium No 73, "The Structure and Evolution of Close Binary Systems", attracted over 110 participants.

ONE reason for the rejuvenation of the subject has been the realisation that most galactic X-ray sources indeed consist of such systems in relatively short lived but highly observable stages of mass transfer between components. Herb Gursky (Harvard University), enjoying his role of Grand Old Man of X-ray astronomy, remarked on the new found respectability of his subject in being awarded the opening day rather than the last afternoon as before; he went on to show that while there is convincing statistical evidence that systems containing type II supernovae subsequently turn into X-ray sources, the situation is quite otherwise for type I. J. B. Hutchings (Dominion Astrophysical Observatory) reported an impressive spectroscopic confirmation of the disputed period of Sco X-1. Earlier this year Gottlieb, Wright and Liller (Harvard University) announced that a photometric study of old Harvard plates taken between 1889 and 1974 showed luminosity variations of only ~ 0.2 mag with a period of 0.787313 d. This remarkable discovery stood in serious conflict with post-X-ray discovery work by other groups and some scepticism had been expressed. However, Hutchings, Cowley and Crampton have now verified the Harvard period by studying the variable radial velocities of He II emission lines. Taken together, these investigations demonstrate the value of the classical and often lengthy programmes eschewed and frequently despised by the "black holier than thou" school of esoteric astrophysicists. Periods considerably less than a day (Cyg X-3 has $P \sim 4.8$ h) pose evolutionary problems for the picture of neutron stars orbiting more or less massive companions and both P. Ostriker (Princeton University)

and B. Paczynski (Polish Academy of Sciences, Warsaw) discussed how the systems might arise. Both required at an earlier stage that rapid mass transfer should produce a system with a neutron star orbiting the core of a distended giant star inside a common envelope. Ostriker envisaged an accretion wake to the neutron star inducing a gravitational drag on its orbit (reminiscent of Chandrasekhar's "dynamical friction"); concomitant heating blew away the envelope. Paczynski imagined the neutron star, through entrainment, acting as a giant paddle, transferring angular momentum from the motion to the common envelope. Both thought the system might at some stage resemble a planetary nebula surrounding a late-type star; whether these remarks were prompted solely by the presence of such puzzles in the literature was unclear. While obviously preliminary and exploratory, these suggestions stimulated much subsequent discussion.

B. Warner (University of Cape Town) presented an outstanding paper on observations of dwarf novae. While covering the many timescales exhibited by these objects, he emphasised the rapid periodicities ($P \sim 16\text{--}34$ s mainly) found by himself and colleagues. Warner and E. L. Robinson (University of Texas, Austin) had previously shown that the pulsations occurred only at or after outburst maxima, a result which everyone agreed placed severe constraints on outburst models (no-one being quite clear however just what the constraints were!) Warner now seems to have found one case of pulsation on the rising branch; it is questionable whether this will be the precursor of similar discoveries or the one exception that seems to exist to every generalisation in this field. Warner announced the discovery of three new types of periodicity in these variables (including one which, as Virginia Trimble remarked, is called "drifting subpulses" in pulsars), thus retaining for these systems the record for the largest number of interesting Fourier components. Almost everyone present now seems prepared to jump on the bandwagon of accretion disk instabilities to explain the quasi-periodic outbursts of these stars; the sceptic might remark that the defects of this explanation have yet to be as thoroughly explored as those of competing mechanisms.

Martin Rees (Cambridge University) gave a typically complete and ultimately sceptical review of accretion disk lore largely in the context of compact X-ray sources, ending with at least six criticisms of generally accepted assumptions as he ran out of time. X-ray emission processes, mass transfer dynamics, evolution and possible

tests of gravitational theories were all crying for attention and getting it in this trendy subject.

The classical topic of contact binaries provided the opportunity for two young workers to impress the audience with their computational skill in following cooperative (or even sometimes uncooperative) evolution of two stars. Both R. Webbink (Cambridge University) and B. Flannery (Institute of Advanced Study, Princeton) have developed modified forms of the evolutionary code of P. P. Eggleton whose method seems uniquely suited to this kind of problem. Webbink studied unsteady mass transfer in close binaries and produced an example in which a catastrophic runaway developed. Flannery showed how contact stars of

almost equal mass evolved to a stage of essentially cyclic thermal instability and mass exchange with mass fraction oscillating between ~ 0.56 and ~ 0.62 in periods of $\sim 10^7$ yr. Such systems seem a very satisfactory explanation for a number of the WUMa "main sequence contact binaries".

All in all, the symposium was a fine blend of observational facts, theoretical explanations and sheer unbridled speculation (at one point Warner remarking that the quality of the arguments led him to conclude that the cow lowing at 2-s intervals in an adjacent field had a density of $\sim 10^6$ g cm $^{-3}$). Commissars Mitton and Whelan marshalled the resources of the Institute splendidly for a meeting that will long be remembered. \square

Comets may conceal chemicals

from John Gribbin

Two of the more speculative of recent suggestions about the place of comets in the Galaxy have now been investigated in some detail by Fred Whipple (*Ast. J.*, **80**, 525; 1975). The ideas are that enough material may be locked up in comets to have a significant effect on the evolving chemistry of the Galaxy, and that γ -ray bursts may be produced by the impact of comets on to neutron stars. The score now seems to stand at Whipple 1, comets 1, with the first possibility still tenable but the second speculation now ruled out of order.

The gamma-ray burst hypothesis always did look a trifle implausible and seemed to require the presence of interstellar comets, since the violent events in which neutron stars are believed to form would be highly likely to disrupt any bound system of comets possessed by the original star. Even though a few comets with hyperbolic orbits have been seen, Whipple's calculations show that for four candidates—the only ones, in a sample of 89 comets with well determined parameters—the chance of any one having arrived on such an orbit from interstellar space is less than 1 in 10^4 , so that for the whole "family" to be interstellar they would be running against odds of 1 in 10^{16} . It is far more likely that the orbits were slightly hyperbolic because "of velocities imparted to solar system comets by the perturbation of passing stars, because of nongravitational effects induced by comet rotation and jet action, because of chance observational errors, or because of systematic displacements of the centre of the observed coma from the direction of the nucleus." But even without wandering through interstellar space free from their parent stars, comets can

play a part in the chemical evolution of the Galaxy. As any galaxy ages, the proportion of metals (by which astronomers mean anything except hydrogen and helium) in its stars increases through nucleosynthesis. Newly forming stars in an old galaxy contain the debris from previous stellar explosions, and do not have the same composition as newly forming stars in a young galaxy. But according to some calculations (B. M. Tinsley and A. G. W. Cameron, *Astrophys. Space Sci.*, **31**, 31; 1974) the mean metal abundance of disk population stars has grown more slowly than expected on the seemingly reasonable assumption that some 2% of the mass from one generation of stars is recycled in the next generation of star formation. Comets could provide a sink for the missing heavy metals (if any really are missing, of course), but Tinsley and Cameron need so many comets that their mass would be 25% of the total mass of gas in the interstellar medium of our Galaxy today—about 1% of the mass locked up in stars.

Rather surprisingly, perhaps, Whipple is able to show that a great mass of comets—more than 1% of the solar mass—could be gravitationally bound to the Sun in a symmetric shell just beyond the radius of the periodic comets and remain completely undetected by present techniques. This provides a lot of leeway for those theorists who wish to, to invoke the presence of such comets to explain discrepancies between their theories and observation, but will not please the more spartan souls who prefer to have well-defined limits on the parameters of the real Universe and who take great pains to fit their models within those rigid limits.

review article

Opiate receptor in normal and drug altered brain function*

Solomon H. Snyder†

Recent biochemical identification of the receptor site for pharmacological actions of opiates helps elucidate how these drugs relieve pain, elicit euphoria and 'addiction', and provides simple, direct approaches to developing potentially non-addicting analgesics. The isolation of a morphine-like peptide which may be a central nervous system neurotransmitter sheds light on normal brain mechanisms regulating pain and emotion.

EXTRACTS of the poppy plant have been used since the days of the Homeric epics medically and recreationally to relieve pain, induce sleep, ease anxiety, for diarrhoea, heart failure and simply to promote a sense of well being. It has long been known that opiates can be addictive and a major goal of opiate research is to develop a non-addictive opiate analgesic. Although non-opiate pain killers such as aspirin are useful in some situations, only opiates seem to be effective in the treatment of severe and protracted pain. Besides such a practical goal, understanding how opiates act may elucidate fundamental questions in pharmacology. Opiates provide the classic paradigm for tolerance and physical dependence, which can occur to a variety of drugs such as alcohol and barbiturates.

What opiates might tell us about normal brain function is a question that prompts consideration of the opiate receptor itself. The fairly stringent chemical requirements for opiate activity, the fact that opiate effects are highly stereospecific and that some opiates, such as etorphine, are so potent that they act in doses even lower than LSD, all suggest that opiate actions must involve highly selective sites or "receptors" in the brain. The existence of opiate antagonists also favours the receptor concept. Opiate antagonists are drugs, closely related in structure to the corresponding opiate analgesics, which may have little or no analgesic or euphoric effect themselves but which can completely reverse action of opiate analgesics. It seems as if the antagonists occupy opiate receptor sites, doing nothing themselves, but preventing access of opiate analgesics. If specific opiate receptors exist in the brain, one would assume that they were created for some normally occurring substance. Indeed, researchers have identified a normally occurring morphine-like factor in the brain with high affinity for specific opiate receptor sites. The distributions of the morphine-like factor and the opiate receptor itself correspond in part to certain pain pathways in the brain,

suggesting that the morphine-like factor may be a neurotransmitter for pathways in the brain mediating pain and emotions. A detailed understanding of such systems might help elucidate some riddles of addiction.

Demonstrating the opiate receptor

The most direct way to identify receptor sites is to measure the binding of radioactive drugs to brain tissue. Like most chemicals, however, opiates bind to almost any biological or non-biological membrane so that nonspecific binding, not associated with the receptor, greatly exceeded any receptor binding in most early studies. Goldstein *et al.*¹ enunciated the criterion that pharmacologically relevant opiate receptor binding should, like opiate analgesic effects themselves, be stereospecific.

In our laboratory, we developed simple technical manoeuvres to amplify specific receptor binding and decrease nonspecific binding. Thus, if opiates bind with considerable affinity to their receptor sites, the use of small amounts of drug labelled to high specific radioactivity favours specific, as opposed to nonspecific, binding, whereas washing tissue thoroughly but rapidly after binding preferentially removes nonspecific binding. On this basis, specific opiate receptor binding has been demonstrated to brain and guinea pig intestine²⁻⁴.

But stereospecific binding itself is not a sufficient criterion for the pharmacologically relevant opiate receptor. Some glass filters⁵ and numerous acidic lipids which may or may not be related to the biological receptor^{7,8} bind opiates stereospecifically. To ensure that binding to brain membranes represents receptor interactions that operate *in vivo*, many drugs were shown to exhibit affinity for the opiate receptor which closely parallels analgesic potency, while non-opiate drugs have negligible affinity for the opiate receptor. Ideally, one should compare pharmacological potency and receptor binding in the same system, which is feasible because the ability of opiates to inhibit electrically induced contractions of the guinea pig intestine closely parallels analgesic activity^{9,10}. Affinity of both opiate agonists and antagonists for receptor binding sites is closely similar in brain and guinea pig intestine and pharmacological and binding potencies of many opiate agonists and antagonists in the same strips of guinea pig intestine are well correlated¹¹. Besides supporting the other evidence that binding *in vitro* involves sites that mediate opiate activity

* This paper derives from the second F O Schmitt Lecture in Neurosciences delivered by the author at MIT, October 1974. Studies described here were conducted in collaboration with C. B. Pert, G. W. Pasternak, I. Creese and M. J. Kuhar and were supported by grants from the US Public Health Service.

† Address Departments of Pharmacology and Experimental Therapeutics, and Psychiatry and the Behavioral Sciences, Johns Hopkins University School of Medicine, Baltimore, Maryland 21205

in vivo, these observations shed light on certain basic drug receptor concepts. Some receptor theories postulate that drugs can exert maximal pharmacological responses while occupying only a small fraction of the total number of pharmacologically active receptors. If a substantial portion of opiate receptors does not normally mediate pharmacological responses, and are thus "spare receptors", then there should be major discrepancies between drug concentrations filling a given percentage of binding sites and concentrations required to produce the same percentage of a maximal pharmacological response. Opiate concentrations occupying half the binding sites in the guinea pig intestine correspond closely, however, to those eliciting half-maximal pharmacological responses, whether agonist or antagonist, which suggests that opiate effects can be explained without invoking spare receptors.

Differential receptor interactions of opiate agonists and antagonists

Opiate antagonists are important for several practical and theoretical reasons. Pure opiate antagonists, such as naloxone and naltrexone, are often life-saving antidotes to opiate overdose. Pure antagonists may also be valuable in treating heroin addicts. The notion is to administer a long-lasting pure antagonist, which will produce no analgesia and euphoria of itself, but which will prevent the effects of subsequently administered heroin. Thus deprived of its ability to elicit a 'high', heroin will cease to be attractive to the addict.

Of greater theoretical and practical importance are opiates which are mixed agonist-antagonists, since some of these agents are relatively non-addicting analgesics. The idea of combining antagonist with agonist activity to lessen the addictive potential of an opiate stems from demonstrations that the opiate antagonist nalorphine possesses analgesic, and thus "agonist" properties¹². Unfortunately, nalorphine, cyclazocine, and levallorphan, antagonists 'contaminated' with agonist activity, are not suitable for routine use in treatment of pain, because at analgesic doses they often produce anxiety, agitation, and psychotomimetic effects. Antagonists with yet more agonist activity, referred to here as mixed agonist-antagonists, have been more promising. Pentazocine, a mixed agonist-antagonist, is already clinically marketed and relieves pain with a low incidence of psychotomimetic effects and with relatively little propensity to produce physical dependence and compulsive craving. Several other mixed agonist-antagonists, while not yet in routine clinical use, offer promise as relatively non-addicting analgesics.

Traditional opiate antagonists differ chemically from agonists only in the substitution of an N-allyl, N-cyclopropyl or related group for the N-methyl of agonists. It is quite difficult to predict chemical features which result in a mixed agonist-antagonist. In our early studies of opiate receptor binding with buffer solutions lacking sodium, agonists and antagonists bound with similar affinity³. Later, we discovered that low concentrations of sodium enhance receptor binding of antagonists but decrease the binding of agonists^{13,14}. The effect of sodium is highly specific. It can be mimicked to some extent by lithium, whose atomic radius is similar to that of sodium, but not by other monovalent cations such as potassium, rubidium or caesium. Sodium seems to accelerate the rate at which antagonists bind to the receptor¹⁵ and to speed the dissociation of agonists from the receptor¹⁴. To evaluate the influence of sodium on receptor interactions of a wide range of opiate agonists and antagonists, we measured the extent to which sodium alters the ability of drugs to inhibit receptor binding of ³H-naloxone. The resultant "sodium response ratio" is the ratio of the concentration of drug which inhibits ³H-naloxone binding 50% in the presence of sodium to the

comparable concentration when sodium is omitted from the incubation medium. This sodium response ratio differentiates opiate agonists and antagonists. For pure antagonists, such as naloxone, the ratio is 1, while for a variety of opiate agonists, the ratio is between 12 and 60. Antagonists which are 'contaminated' with some agonist activity have ratios somewhat greater than 1 but less than 3. The mixed agonist-antagonists we examined have ratios between 3.3 and 6.4, clearly in an intermediate area.

Thus it seems possible to predict the pharmacological properties of different opiates simply by measuring receptor interactions in the presence and absence of sodium, affording a rapid and inexpensive screen for mixed agonist-antagonist 'non-addicting' analgesics. Chemists need not synthesise hundreds of grams of drug for screening in intact animals; a fraction of a milligram will suffice.

Model of opiate receptor function

The selective and pharmacologically relevant influence of sodium on opiate receptor binding seems an integral feature of receptor functioning. Sodium seems to increase and decrease respectively the numbers of antagonist and agonist receptors. Since opiate agonists and antagonists are so similar chemically and compete with each other for receptor binding, we postulate that both drugs bind to the same receptor but that the opiate binding site can vary as the receptor is transformed between two conformations^{14,16,17}. With normal body sodium levels, the receptor is largely in the "sodium" state for which antagonists have a selectively high affinity, whereas opiate agonist actions take place when agonists bind with their selectively high affinity for the "no-sodium" state. Antagonists block morphine actions by occupying sodium states of the receptor and shifting the equilibrium to reduce the number of no-sodium receptors available for morphine. Although agonists and antagonists have selective high affinity for no-sodium and sodium states of the receptor respectively, mixed agonist-antagonists would have similar affinities for the two forms.

The interconversion of the two forms of the opiate receptor presumably involves folding, unfolding, aggregation, disaggregation or other modifications in protein structure, since the exquisite sensitivity of receptor binding to proteolytic enzymes¹⁸ indicates that the opiate receptor is proteinaceous. One might expect protein-modifying reagents and enzymes that affect protein structure to alter the interconversion of receptor sites. Since the opiate receptor should normally be largely in the antagonist or sodium state, agents interfering with receptor interconversion should selectively reduce agonist binding. Consistent with these predictions is the observation that protein-modifying reagents and proteolytic enzymes in low concentrations do selectively reduce opiate agonist binding with negligible effects on antagonist binding¹⁹⁻²¹. The effects of protein-modifying reagents and enzymes seem to be directly related to sodium binding by the opiate receptor, for the reagents and enzymes increase the sensitivity of opiate agonist binding to inhibition by sodium.

Divalent cations may also have a role in the normal functioning of the opiate receptor. Low, physiological, concentrations of manganese and magnesium affect the opiate receptor in a fashion diametrically opposite to sodium; they selectively increase the binding of opiate agonists, by reducing receptor sensitivity to sodium²². Divalent cations act selectively; for while manganese, magnesium and nickel are active, calcium fails to enhance opiate agonist binding. The influence of chelating agents indicates that endogenous divalent cations regulate opiate receptor functions. Thus, treating brain membranes with EDTA, which chelates most divalent cations, lowers opiate agonist binding, while EGTA, which chelates calcium but not manganese and magnesium, has no influence on receptor binding.

The postulated interconversion of agonist and antagonist

conformations and the influence of sodium resemble general models for neurotransmitter receptor behaviour²²⁻²⁵. Normally receptors sites are in the antagonist or "off" conformation. Synaptic transmission occurs only when a compound binds selectively to the agonist conformation of the receptor. One or the other of the receptor states possesses a binding site for the ion whose conductance is altered in synaptic transmission. When the neurotransmitter attaches to the receptor, the binding of this ion is altered to produce the appropriate change in ionic conductance. If the endogenous morphine-like substance is a neurotransmitter, one would speculate that sodium is the ion whose conductance is changed by synaptic activity.

Direct evidence for selective interactions of an ion and receptor binding in synaptic transmission has been obtained for the influence of chloride on glycine receptor binding. Receptor sites for glycine, a major inhibitory neurotransmitter in the mammalian central nervous system, can be labelled with radioactive strychnine, a potent glycine antagonist²⁶. Chloride is the ion whose conductance is increased by the inhibitory synaptic actions of glycine. Chloride and other anions inhibit the binding of strychnine to the glycine receptor in proportion to their ability to mimic the synaptic activities of chloride²⁷.

Regional mapping

Brain functions whose distributions parallel those of opiate receptors may be implicated in opiate actions. Because opiates elicit analgesia, brain structures mediating pain are natural suspects. Sharp, prickly pain, which can be discretely localised, is conveyed by a laterally located sensory pathway with somatotopic representation in the ventrobasal thalamus among other regions. Slower, more chronic and poorly localised burning pain involves multisynaptic, slowly conducting, medially located pathways, especially the palaeospinothalamic and spinoreticulodiencephalic pathways. These lack somatotopic representation and include areas of the brain such as the periaqueductal grey, the medial nuclei of the thalamus and several parts of the limbic system²⁸.

Opiate receptor binding varies dramatically throughout the monkey and human brain^{29,30}. The amygdala binds most, but only slightly more than the periaqueductal grey of the midbrain, hypothalamus and medial thalamus. Receptor binding in the caudate nucleus is also high. Within the cerebral cortex there are marked variations: the frontal cortex for example binds more than four times the amount of opiate bound by the precentral, postcentral gyri and occipital pole. Receptor binding is very low in the spinal cord, cerebellum and white matter.

This map closely resembles the distribution of palaeospinothalamic and spinoreticulodiencephalic pain pathways, and certain of these areas, especially the periaqueductal grey, correspond to those in which implantation of morphine most effectively produces analgesia³¹. Opiate antagonists elicit withdrawal symptoms in addicted animals best when implanted in the medial thalamus, which is also very rich in opiate receptors³². The amygdala, apparently an exception not classically associated with pain pathways, may relate to affective components of pain since electrical stimulation of the amygdala does produce fight and flight reactions. Euphoric actions of morphine may be mediated by the amygdala and other areas of the emotion-regulating limbic system rich in opiate receptors.

Recent autoradiographic studies provide even more precise localisation of opiate receptor sites³³. For such studies it was first necessary for us to achieve reliable techniques for labelling receptors in the intact animals³⁴. After intravenous administration of ³H-diprenorphine, an extremely potent antagonist, 80% or more of radioactivity accumulating in the brain is associated with opiate receptor sites³⁵. For successful autoradiography, diffusion of the radioactive drug away from the receptor site during the fixation

process must be prevented, a difficult task with a drug such as an opiate which does not form covalent chemical linkages to tissue proteins during fixation. In our studies, fixing tissue at very low temperature prevents leakage of ³H-diprenorphine from receptor sites so that essentially all autoradiographic grains are associated with the opiate receptor³³. Grain density parallels the regional distribution of the opiate receptor as determined by dissection and biochemical assays. At a microscopic level, opiate receptor binding is even more discretely localised (Table 1). At one level of the midbrain, grains are highly concentrated over the locus coeruleus with much lower grain counts in closely adjacent nuclei. Interestingly, small doses of morphine slow firing rates of locus coeruleus cells but not adjacent cells³⁵. Since the locus coeruleus consists almost exclusively of noradrenaline cell bodies, its high density of opiate receptors may explain the numerous reports of effects of opiates on the metabolism of biogenic amines including noradrenaline³⁶. At another level of the midbrain, grains concentrate over the zona compacta of the substantia nigra, whereas the adjacent zona reticulata of the substantia nigra has very few receptor grains. The zona compacta but not the zona reticulata consists exclusively of dopamine cell bodies. Thus both major catecholamine systems on the brain are intimately related to opiate receptor sites. An association with major sensory systems in the central nervous system is indicated by the sharp band of opiate receptor grains overlying the substantia gelatinosa in the lower brain stem and spinal cord³³. The substantia gelatinosa is an important "way station" for the upward conduction of sensory information relating to pain.

Table 1 Distribution of autoradiographic grains labelling the opiate receptor in coronal sections of rat brain

Region	Autoradiographic grains per 100 μm^2
Nucleus caudatus putamen	
"Streak" ventral to corpus callosum	11.5
"Clusters"	10.5
Low density areas	1.7
Fibres	1.2
Substantia gelatinosa (spinal cord)	10.4
Locus coeruleus	10.0
Amygdala medialis	6.5
Amygdala centralis	5.8
Zona compacta of substantia nigra	6.5
Thalamus medialis	5.5
Periventricular substance	5.2
Habenula	5.1
Lateral habenula	5.0
Nucleus periventricularis (of hypothalamus)	3.8
Nucleus ventromedialis (of hypothalamus)	2.8
Dentate gyrus	2.1
Motor cortex	2.0
Zona reticulata of substantia nigra	1.9
Hippocampus	1.7
Corpus callosum	0.7
Fimbria	0.8
Ventricle III	1.3
Pyriform cortex	1.1
Cerebellum	0.8
Nucleus of cranial nerve V	0.8

These data are derived from the study of Pert, Kuhar and Snyder³³. Rats (170 g) were injected with 125 μCi of ³H-diprenorphine (13 Ci mmol^{-1}), killed at 1 h and brains rapidly cut into 3-4 mm coronal sections, placed on microtome chucks and lowered slowly into liquid nitrogen "slush". Sections of 4 μm thickness were cut at -18°C in a Harris cryostat microtome and transferred by "thaw-mounting" in the dark to slides already coated with Kodak NTB-3 emulsion. After 5 weeks of exposure at low humidity (4°C) in a dark lead-lined cabinet, slides were developed at 17°C in Dektol for 2 min. Development was terminated by Kodak Liquid Hardener and slides were fixed in hypo (Kodak). After washing in running tapwater, sections were stained with pyronine Y, dried, mounted with Permount and viewed with a Zeiss Universal microscope. Control slides prepared for positive and negative chemography showed no significant fading of latent images or spurious generation of grains after 60 d of exposure. Grain counts are the means of 2,400 μm^2 areas.

Table 2 Regional localisation of the morphine-like factor and opiate receptors in bovine and rat brain

	Morphine-like factor (U per mg protein)	Opiate receptor binding (c.p.m. per 0.1 mg protein)
Bovine		
Caudate	480	320
Hypothalamus	250	282
Spinal cord	140	205
Pons	135	231
Cerebral cortex (Parietal)	80	173
Thalamus	75	179
Cerebellum	50	86
Medulla oblongata	50	88
Corpus callosum	10	61
Rat		
Caudate	480	900
Brainstem (midbrain)	140	220
Cerebral cortex	80	210
Cerebellum	None	None

Data are derived from the study of Pasternak and Snyder⁴¹. In assays for the morphine-like factor, brains were homogenised in ten volumes 0.32 M sucrose with a Potter-Elvehjem homogeniser, and centrifuged at 100,000g for 1 h. The pellet was resuspended in 2 volumes of 10 mM Tris-HCl buffer (pH 7.7 at 25 °C) immersed in a bath of boiling water for 15 min, recentrifuged at 100,000g for 1 h and the supernatant assayed by adding 50–200 µl to an opiate receptor binding assay with ³H-naloxone and 1 mM MnCl₂. Opiate receptor assays were performed as previously described²⁰. The experiments were replicated four times with less than 20% variation between experiments.

Mapping opiate receptor sites by autoradiography is still in a preliminary stage. It is however already clear that this information will help greatly in elucidating the physiological and pharmacological roles of opiate receptor sites. Neurophysiologists who would like to record from cells containing opiate receptor sites ought to focus on the locus coeruleus, the zona compacta of the substantia nigra and other areas enriched in these receptors.

The endogenous morphine-like factor

Man was not made with morphine in him. Is the opiate receptor 'designed' for a normally occurring morphine-like substance, perhaps a neurotransmitter? If so, such a system is widespread among animals. Opiate receptor binding with almost identical substrate specificity has been detected in the central nervous system of all vertebrates, and the most primitive fish have as many opiate receptors as mammals including man³⁷. Strikingly, no opiate receptor binding can be demonstrated in any invertebrates, which may indicate a relationship of the opiate receptor to known differences in patterns of vertebrate and invertebrate neuronal connections. The possibility that the opiate receptor is associated with a neurotransmitter system is strengthened by subcellular fractionation studies which indicate that in mammalian brain homogenates opiate receptor binding is most enriched in synaptosome fractions containing nerve endings with their associated postsynaptic membranes³⁸. When these are subjected to hypotonic lysis, opiate receptor binding is recovered primarily in the synaptic membrane fraction, as would be expected for a neurotransmitter receptor³⁸. A direct approach to identifying a possible neurotransmitter associated with the opiate receptor was adopted by Hughes³⁹, who found in brain extracts a substance which mimics the ability of morphine to inhibit electrically induced contractions of smooth muscle preparations such as the mouse vas deferens or guinea pig intestine, while Terenius⁴⁰ and Pasternak and Snyder⁴¹ reported that brain extracts compete for opiate receptor binding. The substance studied

by both approaches seems to be the same or very similar. The morphine-like factor or "enkephalin" is a peptide, degraded by carboxypeptidase A and B as well as leucine-aminopeptidase and to a lesser extent by chymotrypsin but not by trypsin^{39,41,42}. In opiate binding assays, the material behaves like an agonist, since its ability to compete for binding is impaired by sodium and protein modifying reagents but enhanced by manganese⁴¹. Its regional distribution in calf, rat and rabbit brain is closely similar to that of the opiate receptor itself (Table 2)³⁸⁻⁴². Preliminary chemical analysis indicates that the morphine-like factor contains three residues of glycine and one each of phenylalanine, tyrosine and methionine and may also contain tryptophan^{39,42}. A chemically different peptide, which also mimics the effect of morphine on smooth muscle, has been isolated from pituitary glands⁴³.

If the morphine-like factor is a neurotransmitter, how might it affect postsynaptic cells? Morphine and other opiates applied iontophoretically to single cerebral cortex cells inhibit firing in proportion to their pharmacological potency with marked stereospecific actions and antagonism by naloxone, suggesting that the morphine-like factor may be an inhibitory transmitter⁴⁴. Cells of rats addicted to morphine are no longer inhibited by administered morphine and may even show a paradoxical excitation. Because these changes with addiction occur at the opiate responsive cell itself, the locus of the fundamental alteration in opiate addiction would seem to be at the level of the cell membrane possessing the opiate receptor.

Possible mechanisms of addiction

The term "addiction" is not easily defined. Most people consider opiate addiction to comprise three major elements: tolerance, physical dependence, and compulsive craving. Tolerance means simply that, after prolonged administration of a drug, the organism can "tolerate" more of it, that is, it is now less sensitive to the drug than before. Physical dependence refers to the fact that when the drug is withdrawn or when the animal or person is treated with an opiate antagonist, withdrawal symptoms become evident which are usually in a direction opposite to the initial effects of the drug. Thus whereas morphine produces pupillary constriction, constipation and sedation, during withdrawal the pupils are dilated and there is diarrhoea and central excitation. Compulsive craving is very difficult to evaluate; it refers to the addict's propensity for the drug even long periods after he has been physically withdrawn. Just as tolerance can be looked on as a state of decreased sensitivity to opiate agonists, so in physical dependence animals and humans become more sensitive to antagonists. Withdrawal symptoms can be elicited by much lower doses of antagonists in severely than in mildly addicted animals.

There are two types of model which explain opiate addiction; one of them involves a change at the level of the opiate receptor or closely allied structures, whereas the other requires no such alterations⁴⁵⁻⁴⁹. In the latter model, one presumes that morphine suppresses some neuronal system in the brain. To compensate, a completely separate system increases its activity to counteract the suppressive action of morphine; whereupon the organism is "tolerant". When morphine is withdrawn, the "overactive" second system produces withdrawal symptoms.

Hypersensitivity to antagonists coupled with subsensitivity to agonists in addiction is reminiscent of the properties of the sodium or "antagonist" state of the opiate receptor as contrasted to the no-sodium or "agonist" state. It may be speculated that tolerance and physical dependence reflect a change in the opiate receptor so that it is less capable of assuming the agonist form, favouring instead the antagonist, sodium form. If this were so, addicted animals should be "subsensitive" to opiate agonists, since the receptor would

be less frequently in the "agonist" state to mediate drug effects. Similarly, the organism would be supersensitive to antagonists because of the predominant sodium or antagonist state of the receptor. Though opiate receptor assays both *in vitro* and *in vivo* have failed to show systematic changes related to the addicted state^{13,50}, it is conceivable that such a subtle alteration may be reflected only in membrane properties which occur secondarily to the binding itself. In this connection, recent studies of opiate effects on a neuroblastoma-glioma hybrid in cell culture are illuminating. Opiate agonists, in proportion to their affinity for opiate receptor binding sites in this clone, decrease adenylate cyclase^{51,52} and enhance the accumulation of cyclic GMP⁵³. Opiates also reverse the stimulation of adenylate cyclase by prostaglandin E₁ and adenine⁵¹. Cells exposed chronically to morphine become "tolerant" to the effects of morphine so that previously active doses no longer antagonise the prostaglandin stimulation of adenylate cyclase⁵⁴. When the cells are put into "withdrawal" by naloxone, they become "supersensitive" to the ability of prostaglandin E₁ to stimulate adenylate cyclase, an effect opposite to that of morphine itself in drug-naïve cells⁵⁴.

Of course, one might argue that the cyclic nucleotide changes are relevant only to these cancerous cells of the nervous system in tissue culture. Previously, Collier and Roy⁵⁵ had described a prostaglandin-stimulated adenylate cyclase in mammalian brain which is inhibited by morphine and other opiates, and may be related to the neuroblastoma-glioma effects. Moreover phosphodiesterase inhibitors, which elevate brain cyclic AMP levels, elicit in rats behavioural changes resembling the opiate withdrawal syndrome and which are enhanced by as little as 0.03 mg kg⁻¹ of naloxone^{56,57}.

In summary, recent identification of opiate receptor sites in the central nervous system by biochemical means has spurred a great body of research directed both at pharmacological actions of opiates as well as at the normal functioning of the opiate receptor. An apparently novel peptide neurotransmitter, the morphine-like factor, is being characterised.

As in the case with numerous hormones and neurotransmitters, this morphine-like factor may have as its second messenger cyclic nucleotides, either cyclic AMP or cyclic GMP. Most dramatically, it seems possible that changes in the adenylate cyclase associated with the opiate receptor and conceivably in the opiate receptor itself may begin to answer the many riddles of addiction.

Quark charges and nuclear β -decay

D. H. Wilkinson

Nuclear Physics Laboratory, Oxford University, Oxford, UK

The rate of β -decay is affected by the charges, Q , of the nucleon's constituent quarks. The Salam-Weinberg scheme permits us, in a spirit of adventurous naivety, to conclude that $\bar{Q} = 0.20 \pm 0.10$; this combines with electron and neutrino data to suggest individual quark charges: $Q_p = 0.69 \pm 0.07$, $Q_n = -0.29 \pm 0.15$.

The quark-parton model

The highly successful quark model for the description of hadronic spectra^{1,2} considers baryons as made up of three quarks of baryon number 1/3 and of charges that, in the classical version of the model, are $Q_u = 2/3$ and $Q_d = -1/3$ times the electronic unit but that, in alternative versions, may be integral. The parton model of the nucleon, originally inspired by the scaling

phenomena of deep inelastic electron scattering and by high energy hadronic phenomena^{3,4}, considers the nucleon to be made of "point-like" subunits—the partons. Identification of quarks with partons gives the quark-parton model.

The literal parton model is encouraged by several phenomena such as:

- (1) the surprisingly large abundance of particles produced with high transverse momentum in pp collisions at high energy such as the 28+28 GeV experiments at the CERN ISR⁵;
- (2) the linearity of neutrino-nucleon total cross section with neutrino energy up to $E \simeq 200$ GeV (ref. 6); the latter data indicate that the total effective dimension of the νN interaction, including that of the parton, is less than 0.02 fm which, on comparison with $\langle r^2 \rangle^{1/2} \simeq 0.8$ fm for the nucleon as a whole, suggests that the partons are, at the most, 2–3% of the size of the nucleon that they make up.

That the spin of the partons is $\frac{1}{2}$ follows experimentally from the deep inelastic electron scattering experiments (the Callen-Gross relation)⁶; the experimental ratio of 3:1 between high energy neutrino and antineutrino cross sections on nucleons then shows that the nucleon is composed 95% or more of partons and therefore has very little antiparton content⁶ (some antimatter there must be since forces must make pairs). The Gross-Llewellyn-Smith sum rule for neutrino-nucleon interactions permits the "counting" of the partons; the result of 3.2 ± 0.6 completes the "experimental" identification of the quark-parton model⁶.

Of course, one is not obliged to talk this language at all. One can replace the literal constituent quarks by current quarks and one can replace the literal point-like partons by statements about singularities of relevant commutators on the lightcone. But the quark-parton model provides, at least, a legitimate, and attractively picturesque, framework for the parameterisation of particle structure and, within that framework, it may be asked whether an internal consistency with one or other version of the model is found. In this article I adopt the simple quark-parton viewpoint, ignore its naiveties and illuminate it through ordinary low energy nuclear β -decay.

The essential point is that β -decay does not involve solely the weak interaction; electromagnetic forces must be simultaneously at work providing the "radiative corrections". The radiative corrections involve not only the nucleon as a whole but also its constituent quarks so the magnitude of the radiative corrections must involve the charges of the quarks; this article makes statements about those charges.

We proceed through a hierarchy of hypotheses: (1) conservation of the vector current⁷; (2) μ -e universality in the Cabibbo sense⁸; (3) unification of the weak and electromagnetic interactions in the Salam-Weinberg sense⁹. Without (1) and (2) the present remarks fall to the ground. Adoption of (3) makes our evaluation specific but it could be redone for any other version of the gauge theories than Salam-Weinberg and any other version of the quark model than those used by Sirlin¹⁰ in his contingent treatment of the radiative corrections. In view of the uncertainties attaching to (3) the present analysis should perhaps be regarded as no more than illustrative of the sort of information as to the quark charges that will ultimately be extracted from nuclear β -decay; but if, as seems possible, Sirlin's result for the radiative corrections has a rather general validity, we may already regard the present outcome as of interest. We find:

$$\bar{Q} = 0.20 \pm 0.10$$

where \bar{Q} is the mean quark charge of the nucleon (compare $1/6$ expected for the classical non-integrally-charged quark model^{11,2} and $1/2$ for integrally-charged quark models).

The radiative corrections

Briefly, it is clear^{11,12} that the radiative corrections of order α to nucleon β -decay may be divided into two parts: the well-understood explicit "outer" correction δ_B^a is energy-release dependent but independent of nucleon structure and β -decay anatomy

and may therefore be absorbed into the phase-space factor; the "inner" correction Δ_B^a depends on structure and anatomy but is energy-release independent so may be absorbed into the coupling constant. We particularise to vector β -decay and write:

$$g_{\beta V}^R = g_{\beta V}(1 + \frac{1}{2}\Delta_{\beta V}^a)$$

where $g_{\beta V}$ is the vector coupling constant as we should know it but for the radiative corrections.

Our hope of quark-charge information therefore resides in $\Delta_{\beta V}^a$. The trouble about $\Delta_{\beta V}^a$ used to be the divergencies that it contained: these were severe and largely intractable, even when the primitive point 4-fermion interaction $N \rightarrow N\bar{\nu}e$ (ref. 13) was replaced by mediation through the hypothetical intermediate vector boson $N \rightarrow N W; W \rightarrow e\bar{\nu}$ (ref. 14) and when quark structure was introduced¹⁵. The new unified weak/electromagnetic gauge theories⁹ have, however, changed all that: $\Delta_{\beta V}^a$ is now divergenceless apart from a single term that can, unexceptionably, be absorbed into the weak coupling constant as a universal renormalisation in direct analogy to the hallowed practice in quantum electrodynamics.

$\Delta_{\beta V}^a$ must be evaluated in the context of specific quark models and specific formulations of the unified theory; so far only two classes of quark model have been studied in detail¹⁰ and one formulation of weak interaction theory, namely the Salam-Weinberg scheme⁹; however, the general form of $\Delta_{\beta V}^a$ has remained remarkably stable against changes in its conceptual background^{10,13-15} and it seems probable that something very like the present form will remain no matter what the quark and weak interaction pictures maybe come. We therefore conduct our present analysis using Sirlin's¹⁰ evaluation of $\Delta_{\beta V}^a$, recognising that the Salam-Weinberg scheme on which it is based is by no means proven and recognising the limited range of quark pictures for which it has been shown to be valid but believing that something very like it will continue to hold and therefore regarding the conclusions that we tentatively draw here as being, at the least, illustrative of the quality of information that can, in principle, be extracted from β -decay data.

We can choose whether we want to use β -decay to tell us about nucleon structure or about the anatomy of β -decay. The earlier viewpoint, pioneered by Blin-Stoyle, to whom a great deal is due in studies of the present type¹⁶, was that β -decay suggested mediation of the weak interaction by a very heavy intermediate vector boson; the success of the gauge theories now seems to recommend that we tentatively take the weak interaction for granted and use β -decay to tell us about nucleon structure; this is the viewpoint of my present note.

What is of interest is not so much $\Delta_{\beta V}^a$ itself as $\Delta_{\beta V}^a - \Delta_\mu^a$ where Δ_μ^a is the analogous quantity involved in muon decay. Sirlin¹⁰ finds

$$\Delta_{\beta V}^a - \Delta_\mu^a = (\alpha/2\pi) \{3\ln(m_Z/m_N) + 6\bar{Q}\ln(m_Z/m_A)\}$$

The first term in curly brackets comes from the vector part of the hadronic weak current; the second term comes from the axial part of the hadronic weak current which contributes to the overall vector amplitude because it can combine appropriately with the isoscalar part of the electromagnetic current. m_N is the nucleon mass and m_Z that of the neutral intermediate vector boson, Z^0 , of the Salam-Weinberg scheme (the mass of the charged W^\pm drops out in $\Delta_{\beta V}^a - \Delta_\mu^a$). m_A is the mass of some suitable "axial" structure and is conventionally awarded the mass of the A_1 -meson for which we take 1,300 MeV (ref. 17 and M. G. Bowler, private communication); this is the energy above which the asymptotic form for the axial current part of the second rank tensor that describes the exchange of virtual photons between nucleon and decay electron becomes valid. m_A is uncertain but it would have to be raised to 4.5 GeV to shift our present conclusion as to \bar{Q} by its error limit.

When we are concerned with nuclear, as opposed to nucleon,

β -decay "outer" radiative corrections arise in addition to δ_β^a . If one writes them as δ_β^{za} a general restriction is $m \geq n$ (ref. 18). By the Ademollo-Gatto theorem¹⁹, which says that the renormalisation of coupling constants is of second order in the multiplet mass splittings, there is no term linear in $Z\alpha$ (ref. 18). Higher terms with $m = n$ and not involving nuclear excitation are negligible²⁰; those involving nuclear excitation are treated

such as has been occasionally suggested as an explanation for the anomalously high rate of $\eta \rightarrow \pi$ decay, would have negligible effect²³).

For such $J^\pi = 0^+$, $T = 1$ decays, including all radiative corrections, we can therefore write:

$$f^R t = \frac{\pi^3 \hbar^7 \ln 2}{m^6 c^4 g_{\beta V}^2 (1 - \epsilon)} = \frac{6.153 \times 10^{-25}}{g_{\beta V}^2 (1 - \epsilon)} \text{ erg}^2 \text{ cm}^6 \text{ s}$$

Fig. 1

separately as small modifications to the nuclear matrix element as I shall discuss in detail. Of the terms with $m = n+1$, $\delta_\beta^{za^2}$ and $\delta_\beta^{za^3}$ have been evaluated^{21,22} and the remainder shown to be negligible (for the nuclei of present concern). Terms with $m = n+2$ and so on are also negligible^{21,22}; we therefore, with an overall accuracy of better than 0.1%, replace the ordinary phase space factor f (which already contains the effect of the gross Coulomb field of the nucleus in distorting the outgoing electron wave) by its outer-radiative-corrected version f^R :

$$f^R = f(1 + \delta_\beta^a + \delta_\beta^{za^2} + \delta_\beta^{za^3})$$

(The δ_β terms are designed to be combined in this way)

We remember that other radiative effects are contained in $g_{\beta V}^R$ and in the modification of the nuclear matrix element.

Pure vector nuclear β -decay

β -decay within isospin multiplets of $J^\pi = 0^+$ is pure vector because there is no nuclear spin to flip. Under complete charge independence the matrix element would be given purely by the geometrical Clebsch-Gordan factor in the isospins and, for the cases of $T = 1$ with which we are here concerned, would take the value $\sqrt{2}$. In practice, charge independence is relaxed by the implicit and explicit effects of the Coulomb force so that the matrix element must be multiplied by $(1 - \epsilon)^{1/2}$ where we expect, by the Ademollo-Gatto theorem, that ϵ should go roughly as Z^2 . (Non-Coulomb breaking of charge independence,

where t is the half life (corrected for branching and orbital electron capture) and where there is no error in the numerical value to the accuracy stated.

f itself must be computed with care and must involve solving the Dirac equation in a field generated by a nuclear charge distribution of finite size, consistent with electron scattering and muonic X-ray data, screened by the atomic electrons, and convoluting the resultant positron and associated neutrino wavefunctions with nucleonic wavefunctions generated in a realistic nuclear potential. This task has been performed with an overall reliability of better than 0.05% (refs 24 and 25).

The ϵ have been computed several times recently and their associated error is probably better than 0.1%; this matrix element correction can also be derived empirically from the experimental data (see section under that heading), as reviewed in the section headed ϵ -values, when it shows good agreement with the directly-computed values.

The experimental data relate to the decay of ^{14}O , $^{26}\text{Al}^m$, ^{34}Cl , $^{38}\text{K}^m$, ^{42}Sc , ^{46}V , ^{50}Mn and ^{54}Co for each of which bodies ft is determined to better than $\pm 1/3\%$. The set shows excellent internal consistency and we conclude

$$g_{\beta V}^R = (1.4116 \pm 0.0008) \times 10^{-49} \text{ erg cm}^3$$

Conserved vector current and the Cabibbo angle

The excellent internal consistency of the eight accurately-measured vector transitions agrees with the hypothesis of the conserved vector current⁷ in that vector β -decay suffers no renormalisation by mesonic exchange effects and may therefore be equated with muon decay if we extend the hypothesis to a universality of the weak coupling constant in analogy to that of electric charge. In adopting the hypothesis of universality we must follow Cabibbo⁸ and divide the hadronic weak current into strangeness-conserving and strangeness-changing parts so that our expectation becomes:

$$g_{\beta V} = g_\mu \cos \theta_C$$

where θ_C is the Cabibbo angle that splits the hadronic decay strength between $\Delta S = 0$ and $\Delta S = 1$.

This expectation is not vitiated by W-boson propagator corrections which are of order $(m_\mu/m_W)^2$ or less, that is less than 0.01% for $m_W > 10 \text{ GeV}$ as experimentally demonstrated⁶, nor by finite nucleon size effects which amount to (2/21)

Table 1

Decaying body	$E_0(\text{keV})$	$t(\text{s})$	$f^R t(\text{s})$	$f t \text{ s}$
^{14}O	$1,809.86 \pm 0.36$ (ref. 24)	71.136 ± 0.031 (ref. 24)*	$3,094.3 \pm 3.0$	$3,090.3 \pm 4.3$

* And J. A. Becker, R. L. Chalmers, B. A. Watson, and D. H. Wilkinson, unpublished.

$W_0^2 \langle r^2 \rangle_{\beta\gamma}$, where W_0 is the energy release in natural units, 0.01% in the worst of our present cases.

The Cabibbo angle is most naturally determined from semi-leptonic hyperon decay on which a large and excellently self-consistent body of data exists²⁶ and which, after a small allowance for SU(3) symmetry breaking²⁷, yields $\sin\theta_c = 0.238 \pm 0.005$. Another approach to θ_c comes from K_{e3} -decay which, interpreted conventionally using the Klein-Gordon equation for the pion, yields²⁸ $\sin\theta_c = 0.223 \pm 0.003$. Since K-decay is not so closely connected to the nucleon-decay problem as is hyperon decay, since it has fewer internal consistency checks and since there is some doubt about the appropriate treatment of the pion²⁹, we do not try to combine the two values of $\sin\theta_c$ but rather accept the K_{e3} value as evidence that the hyperon value may be a bit on the high side and so reduce the latter by its own standard deviation and adopt

$$\sin\theta_c = 0.233 \pm 0.005$$

Muon decay

The mean-life of the muon, τ_μ , is given by

$$\tau_\mu = \frac{192\pi^3 \hbar^7 (1 - \delta_\mu^a)}{m_\mu^5 c^4 (1 - 8m_e^2/m_\mu^2) g_\mu^R{}^2}$$

where δ_μ^a is the "outer" radiative correction of order α , the analogue of δ_β^a , and is given by^{29,30}

$$\delta_\mu^a = -(\alpha/2\pi) (\pi^2 - (25/4))$$

δ_μ^a , and higher corrections have been evaluated only incompletely³¹ but seem unlikely to introduce changes of more than 1 part in 10^4 in τ_μ . g_μ^R contains the effect on τ_μ of the anatomy of the β -decay process

$$g_\mu^R = g_\mu (1 + \frac{1}{2} \Delta_\mu^a)$$

Recent experiments give

$$\begin{aligned} \tau_\mu &= 2197.3 \pm 0.3 \text{ ns} \quad (\text{ref. 32}) \\ &= 2197.11 \pm 0.08 \text{ ns} \quad (\text{ref. 33}) \end{aligned}$$

so that

$$g_\mu^R = (1.4358 \pm 0.0001) \times 10^{-49} \text{ erg cm}^3$$

where the error has been inflated to take account of the uncertainties in δ_μ^a .

$$\Delta_{\beta\gamma}^a - \Delta_\mu^a$$

We bring together the various values quoted above to find

$$\Delta_{\beta\gamma}^a - \Delta_\mu^a = 2 \left\{ \frac{g_{\beta\gamma}^R}{g_\mu^R \cos\theta_c} - 1 \right\} = (2.19 \pm 0.27) \%$$

which we could confront, to find \bar{Q} , with Sirlin's above-quoted theoretical expression for $\Delta_{\beta\gamma}^a - \Delta_\mu^a$, if we knew m_Z .

M_Z

Within the Salam-Weinberg scheme, that we have adopted, the mass, m_Z , of the neutral intermediate vector boson that figures in Sirlin's formula for $\Delta_{\beta\gamma}^a - \Delta_\mu^a$ is given by: $m_Z = 74.6/\sin(2\theta_w)$ GeV; θ_w is the Weinberg angle that relates the weak and electromagnetic coupling constants. The scheme is encouraged by the "neutral current" neutrino interactions that for muon-less hadron-producing events, within a quark-parton model such as we consider here, give $\sin^2\theta_w = 0.39 \pm 0.05$ (ref. 34). $\bar{\nu}_e e$ -scattering (to which charged currents can also contribute) gives $\sin^2\theta_w < 0.3$ (ref. 35). $\bar{\nu}_\mu e$ -scattering is not

inconsistent with $\sin^2\theta_w \simeq 0.25$ (ref. 34 and D. H. Perkins, private communication), somewhat smaller and somewhat larger values being admissible. For our present purpose we therefore use:

$$74.6 < m_Z < 100 \text{ GeV}$$

where 100 GeV corresponds to $\sin^2\theta_w \simeq 0.17$ which appears to be safely on the low side.

\bar{Q}

Our experimental $\Delta_{\beta\gamma}^a - \Delta_\mu^a$ and the above-adopted m_Z are confronted with Sirlin's formula in Fig. 1; we derive: $\bar{Q} = 0.20 \pm 0.10$. (The largest component in the error comes from that in θ_c .)

We repeat the various cautionary remarks about our reliance on the hypotheses listed above, in particular on the Salam-Weinberg scheme, and on Sirlin's derivation of his formula, but within these limits our value of \bar{Q} can be treated as a definite parameter.

Quark charges

$\bar{Q} = 0.20 \pm 0.10$ is consistent with $\bar{Q} = 1/6$ expected for the classical quark model; it is inconsistent with $\bar{Q} = 1/2$ as for integral quarks. Other data relevant to "quark charges" come from a comparison of deep inelastic neutrino and electron scattering; the two show good internal consistency within the quark-parton model and their comparison then permits the statement, if there are no strange constituents to the nucleon, which is a good assumption in view of the evident lack of anti-matter remarked on above: $\bar{Q}^2 = 0.28 \pm 0.03$ (ref. 6) which is consistent with the expectation of the classical quark model: $\bar{Q}^2 = 5/18$.

Putting together \bar{Q} and \bar{Q}^2 , the "experimental" values of the separate quark charges become

$$\begin{aligned} Q_p &= 0.69 \pm 0.07 \\ Q_n &= -0.29 \pm 0.15 \end{aligned}$$

to be compared with the classical values: $Q_p = 2/3$, $Q_n = -1/3$.

It is the especial virtue of the present approach that it is sensitive to \bar{Q} rather than to \bar{Q}^2 .

Experimental data

J. M. Freeman, W. E. Burcham and their colleagues at AERE, Harwell have, for many years, carried out accurate measurements on super-allowed Fermi β -decay. More recently, important contributions have also come from D. E. Alburger, J. C. Hardy and their colleagues at Brookhaven National Laboratory and Chalk River. Old inconsistencies have now disappeared; the present situation, summarised in Table 1, where t has been corrected for branching and electron capture, is one in which considerable confidence may be reposed.

E_0 is the maximum kinetic energy of the positron. f is defined as $f^R(1-\epsilon)$. The ϵ -values have been taken from Table 2 and an error of $\pm 0.1\%$ associated with each. $f t$ should then be a constant if the vector current is conserved; its mean value

Table 2

A	$\epsilon_1\%$ (ref. 43)	$\epsilon_1\%$ (ref. 44)*	$\epsilon_1\%$ (ref. 24)	$\epsilon_2\%$ (ref. 24)	$\epsilon\%$
14	0.04	0.04	0.15	0.05	0.13
26	0.10	0.11	0.12	0.07	0.18
34	0.17	0.18	0.19	0.23	0.41
38	0.21	0.21	0.21	0.16	0.37
42	0.25	0.25	0.31	0.13	0.40
46	0.30	0.29	0.17	0.04	0.29
50	0.35	0.33	0.21	0.03	0.33
54	0.40	0.38	0.27	0.04	0.39

* And A. M. Lane, private communication.

is $\bar{f}t = 3,087.7 \pm 2.3$ s with $\chi^2/\nu = 0.56$ so internal consistency is good.

Alternatively, we may follow the suggestion of the Ademollo-Gatto theorem¹⁹ namely that ϵ should go, *ceteris paribus*, as the square of the mass-splittings within the isomultiplets which, over the range of Table 1, means roughly as $Z^{1.75}$. Fitting to the form: $f^R t = (f^R t)_{Z=0} + aZ^{1.75}$, gives $(f^R t)_{Z=0} = 3,088.5 \pm 3.8$ s in good agreement with $\bar{f}t$. We adopt $3,087.9 \pm 3.5$ s; this leads to the $g_{\beta V}^R$ -value quoted in the text.

The ϵ -values

There is a long history to computation of the ϵ -values⁴¹. Recent estimates are shown in Table 2. ϵ splits into two parts: ϵ_1 is due to the one-body Coulomb force and ϵ_2 to the two-body Coulomb force. The three estimates of ϵ_1 , made by very different methods, agree well among themselves (the third of them has been halved to allow more properly for the parentage spectrum⁴³, except for ⁴²Sc where the parentage is unique). It seems that $\epsilon = \epsilon_1 + \epsilon_2$ as quoted should be reliable to $\pm 0.1\%$.

In vitro synthesis of tRNA precursors and their conversion to mature size tRNA

Violet Daniel, Jacob I. Grimberg & Menachem Zeevi

Department of Biochemistry, Weizmann Institute of Science, Rehovot, Israel

Two *Escherichia coli* tRNA gene clusters, $tRNA_1^{Tyr}$ (su_3^+ and su_3^-) and $tRNA_2^{Tyr}$, $tRNA_2^{Gly}$ (su_3^+), $tRNA_3^{Thr}$, were transcribed in a purified *in vitro* system. Evidence indicates that the adjacent tRNA genes are transcribed together as a common precursor of large size, which, on incubation with crude cell extracts, yields mature tRNA molecules.

It is now generally established that tRNA genes of bacterial and mammalian cells as well as those of bacteriophage T4 are transcribed into large RNA precursor molecules which are subsequently cleaved by specific nucleases to yield mature size tRNA¹⁻⁶. Because of the transient nature of the tRNA precursors, however, only in a few cases have such molecules been isolated *in vivo*^{1,7} and some of them may represent already partially cleaved precursors^{8,9}. Transcription of tRNA genes *in vitro* by purified RNA polymerase has the advantage of producing completely unmodified tRNA precursors and provides an opportunity to study in detail the processing and modification of primary transcription products.

The structural genes for some tRNA molecules are often present on the *E. coli* chromosome as clusters containing identical genes^{10,11}, or genes specifying different tRNAs¹². Two such tRNA gene clusters are being studied: the duplicate genes coding for $tRNA_1^{Tyr}$ (su_3^+ and su_3^-) carried by transducing phage $\phi 80psu_3^{+,-}$ (ref. 13) and the $tRNA_2^{Gly}$ (su_3^+) $tRNA_3^{Thr}$, $tRNA_2^{Tyr}$ genes carried by $\lambda h80T$ phage DNA¹². *In vivo*^{8,14} and *in vitro*^{15,16} studies suggest that these tRNA genes may be transcribed as large RNA precursors. In the

present report the multiple tRNA genes carried by $\phi 80psu_3^{+,-}$ and $\lambda h80T$ phage DNA were transcribed *in vitro* by *E. coli* RNA polymerase as polycistronic tRNA precursors. These precursors were cleaved on incubation with a supernatant fraction prepared from *E. coli*, yielding mature size tRNA molecules. The process of precursor cleavage was analysed using polyacrylamide gel electrophoresis. It was found that the formation of tRNA takes place by way of intermediate size RNA molecules. The mature size tRNA and some of the intermediate precursors were found, using fingerprint techniques, to be similar or identical to those made *in vivo*.

Transcription and processing of $tRNA_1^{Tyr}$ precursor

$\phi 80psu_3^{+,-}$ DNA carrying both suppressor and wild-type $tRNA_1^{Tyr}$ genes was transcribed *in vitro* by RNA polymerase in a reaction mixture containing α -³²P-GTP. After 30 min incubation at 37 °C, RNA synthesis was terminated by the addition of actinomycin D and DNase I. The formation of mature size $tRNA_1^{Tyr}$ from larger precursors was studied by following the processing of the *in vitro* $\phi 80psu_3^+$ RNA transcripts by crude *E. coli* S100 extracts as a function of incubation time.

The synthesised α -³²P-GMP-labelled RNA was extracted from a portion of the reaction mixture (zero time of processing). The rest of the reaction mixture, was incubated with S100 extract from *E. coli*. At different time intervals (5, 10, 20 and 40 min) equal aliquots were removed, the RNA extracted by phenol and precipitated by ethanol. The RNA preparations were separated by electrophoresis on a 5% polyacrylamide-7 M

Fig. 1 Autoradiogram of acrylamide gel separations of cleavage products of RNA transcribed *in vitro* on $\phi 80psu_3^{+/-}$ DNA. $\phi 80psu_3^{+/-}$ DNA (20 μ g) was transcribed in 200 μ l reaction mixture containing: 0.05 M Tris-HCl (pH 7.9), 0.01 M $MgCl_2$, 0.075 M KCl, 1 mM dithiothreitol, 0.4 mM each of ATP, CTP and UTP, 0.3 mM $\alpha\text{-}^{32}P\text{-GTP}$ (2.3 Ci mmol $^{-1}$; Amersham, England) 12 μ g ρ termination factor and 60 U RNA polymerase (1,600 U mg $^{-1}$). The synthesis was initiated after 5 min pre-incubation at 38 $^{\circ}C$ by addition of nucleoside triphosphates. After 30 min incubation at 38 $^{\circ}C$ the reaction was stopped by the addition of 20 μ g actinomycin D and 4 μ g DNase I (Worthington, Freehold, New Jersey). RNA was extracted from a 30 μ l aliquot of the reaction mixture and run on acrylamide gel to give the electrophoretic pattern for zero time of processing. The rest of the mixture was incubated at 37 $^{\circ}C$ with 400 μ g S100 extract. Aliquots were removed at the times indicated in the figure and fractionated by acrylamide gel electrophoresis on 40 \times 20 cm 5% gels (20:1 acrylamide-bis-acrylamide) containing 7 M urea, in Tris-borate buffer¹⁷ at 175 V for 16–19 h. 9S globin mRNA, 5S RNA and tRNA^{Tyr} were run separately as reference markers and were located by staining the gel with Stains all (Eastman-Kodak). DNA-dependent RNA polymerase was prepared from *E. coli* MRE600 cells¹⁸ and further purified by low salt glycerol gradient centrifugation¹⁹. Termination factor ρ was prepared from *E. coli* MRE600 cells as described by Roberts²⁰. S100 supernatant fraction was prepared from log-phase *E. coli* MRE600 cells suspended in buffer (0.01 M Tris-acetate, pH 7.5, 0.014 M $MgCl_2$, 0.06 M KCl, 6 mM 2-mercaptoethanol) and disrupted in a French press. The extract was centrifuged for 90 min at 105,000g in a Spinco ultracentrifuge and the S100 supernatant obtained was dialysed against the same buffer and stored at $-20^{\circ}C$.

urea gel. An autoradiogram of the gel separation for the RNA preparations is presented in Fig. 1. A single RNA band is observed in the non-processed $\phi 80psu_3^{+/-}$ RNA (band *a* at 0 time of incubation). On incubation with the S100 extract, the intensity of this band decreases. Band *e*, with the mobility of tRNA^{Tyr}, appears only after addition of the S100 extract and increases in intensity with the time of incubation. Attention should be drawn to the fact that band *e* RNA reaches the size of mature tRNA^{Tyr} only after 15–20 min incubation. The varied

dispersity and larger size of band *e* RNA at shorter periods of incubation may be due to insufficient trimming of the additional nucleotide sequences by an exonuclease activity present in the S100 extract. Figure 1 also shows that the maturation of tRNA^{Tyr} is a stepwise process involving the formation of intermediate size RNA molecules. Concomitant with the disappearance of band *a* during incubation with the S100 extract, additional RNA bands *b*, *c*, *d* and *x* are formed, the intermediate character of which is suggested by the fact that during incubation their intensity increases, reaches a maximum and decreases again. This behaviour is clearly seen in the case of band *x* for the incubation periods covered by Fig. 1. For sufficiently long incubation periods all intermediate RNA bands virtually disappear (data not shown).

Transcription and processing of tRNA^{Tyr}, tRNA^{Gly}, tRNA^{Thr} precursor

λ h80T DNA was transcribed *in vitro* by RNA polymerase in a reaction mixture containing $\alpha\text{-}^{32}P\text{-GTP}$. The formation of tRNA molecules from precursors was studied by following the cleavage of the *in vitro* λ h80T RNA by *E. coli* S100 extracts as a function of incubation time. Figure 2 shows that the primary transcription product of λ h80T DNA (0 time of incubation with S100 extract) is composed of RNA molecules of varied size, which remain at the origin or migrate in the 9S region of the gel, and of three distinct bands *a*, *c* and *g*. On incubation with S100 extract, two 4S RNA bands (*e* and *f*) appear, their intensity increasing with time. Band *e* has a mobility corresponding to a tRNA^{Tyr} molecule. Band *f*, as shown later, is actually composed of two tRNA species, tRNA^{Thr} and tRNA^{Gly}, which do not separate on the urea-containing polyacrylamide gel. As observed previously for the formation of tRNA^{Tyr} from the $\phi 80psu_3^{+/-}$ DNA transcript (Fig. 1), the tRNA species in bands *e* and *f* (Fig. 2) appear first as diffuse bands and reach the mature tRNA size only after 15 min incubation. The

Fig. 2 Autoradiogram of acrylamide gel separation of cleavage products of RNA transcribed *in vitro* on λ h80T DNA. RNA synthesis and cleavage by S100 extract was as described in Fig. 1.

† Fragment derived from tRNA $_2^{Tyr}$ (ref. 22).

appearance of the tRNA bands is accompanied by the cleavage of band *a* (Fig. 2). For longer periods of incubation the disappearance of the other bands was also observed (data not shown).

Sequence analysis of tRNA molecules synthesised *in vitro*

The synthesised tRNA molecules were identified by the two-dimensional fingerprint of T_1 RNase digestion fragments²¹. As *in vitro* transcription was carried out with α -³²P-GTP and T_1 RNase cleaves the RNA adjacent to GMP residues, each fragment obtained contains a labelled 3'-terminal GMP. The two-dimensional fingerprint of the tRNA synthesised *in vitro* should therefore be the same as that obtained with the respective uniformly labelled *in vivo* tRNA species. The only exception is the 3'-terminal fragment of the tRNA which contains no GMP and will not be labelled in the *in vitro* transcript. Autoradiograms of the two-dimensional T_1 RNase fingerprints of band *e* (tRNA $_1^{Tyr}$) from Fig. 1 and band *e* (tRNA $_2^{Tyr}$) from Fig. 2 are presented in Fig. 3*a* and *b*, respectively. The two fingerprints are similar to each other and to the T_1 RNase fingerprint of *in vivo* *E. coli* tRNA $_1^{Tyr}$ described by Goodman *et al.*²². The oligonucleotides isolated in the fingerprints were extracted from the DEAE paper and the nearest-neighbour distribution of the labelled GMP in the fragments was determined by alkaline hydrolysis. The results for both tRNA $_1^{Tyr}$ and tRNA $_2^{Tyr}$ synthesised *in vitro* are presented in Table 1 and show that given its position on the fingerprint, each oligonucleotide yielded the nearest-neighbour nucleotide expected, assuming it to be derived from tRNA Tyr (ref. 22).

The tRNA $_2^{Tyr}$ transcribed on λ h80T DNA differs from the tRNA $_1^{Tyr}$ species transcribed on ϕ 80 $psu_3^{+/-}$ DNA by the presence of fragment UCACAG (Fig. 3*b*, spot 21). The tRNA $_2^{Tyr}$ fingerprint also contains the fragments ACUG (spot 20) and UAAAψCUG (spot 18), both derived from the anticodon sequence ACUGUAAAψCUG. Because of replacement of G by a C in this sequence in tRNA $_1^{Tyr}$ su_3^+ the fragment is not cleaved by T_1 RNase and appears as oligonucleotide 19 in Fig. 3*a*. As ϕ 80 $psu_3^{+/-}$ DNA codes both for su_3^- and su_3^+ species of tRNA $_1^{Tyr}$, however, the fingerprint in Fig. 3*a* also contains the spots ACUG (20) and UAAAψCUG

(18) derived from su_3^- . The T_1 RNase-resistant fragment C 2'-O-methyl GG, normally found in *in vivo* tRNA Tyr , is absent from both tRNA $_1^{Tyr}$ and tRNA $_2^{Tyr}$ synthesised *in vitro* (Fig. 3*a* and *b*); the CG (spot 3) observed in both fingerprints derives from the unmodified sequence CCG.

To determine the 3'-terminal sequences of tRNA $_1^{Tyr}$ we have synthesised ϕ 80 $psu_3^{+/-}$ RNA using α -³²P-CTP. T_1 RNase fingerprints of α -³²P-CMP-labelled band *e* RNA reveal a spot with a mobility identical to that of the oligonucleotide AAUCCUCCCCCACCACCAOH observed for *in vivo* tRNA Tyr (ref. 22). The nearest-neighbour distribution of the labelled CMP in this fragment was as expected 2A:2U:7C. Band *d* RNA transcribed on the ϕ 80 $psu_3^{+/-}$ DNA template which migrates in the 5S region of the acrylamide gel (Fig. 1)

Fig. 3 Autoradiogram of fingerprints of tRNA molecules synthesised *in vitro*. *a*, tRNA $_1^{Tyr}$ (su_3^+ and su_3^-) transcribed on ϕ 80 $psu_3^{+/-}$ DNA (band *e* from Fig. 1). *b*, tRNA $_2^{Tyr}$ transcribed on λ h80T DNA (band *e* from Fig. 2). *c*, tRNA $_1^{Tyr}$ (5S) precursor transcribed on ϕ 80 $psu_3^{+/-}$ DNA (band *d* from Fig. 1). *d*, Mixed fingerprint of tRNA Thr and tRNA Gly transcribed on λ h80T DNA (band *f* from Fig. 2). Fingerprint analysis was carried out by extraction of the RNA bands from the gel by homogenisation in 0.5 M NaCl, 0.1 M Tris-HCl, pH 8.0, and 0.01 M EDTA, digestion by T_1 RNase and two-dimensional electrophoresis according to Sanger *et al.*²¹.

was also analysed by the fingerprint method. The autoradiogram presented in Fig. 3c identifies this RNA as a $\text{tRNA}_{1^{\text{Tyr}}\text{su}_3^+}$ precursor. The nearest-neighbour analysis of the T_1 RNase oligonucleotides obtained from the fingerprint separation is similar to that of the *in vivo* 5S precursor of $\text{tRNA}_{1^{\text{Tyr}}\text{su}_3^+}$ described by Altman and Smith⁷. The fingerprint of the 5S $\text{tRNA}_{1^{\text{Tyr}}}$ precursor synthesised *in vitro* does not contain the ACUG fragment and seems therefore to be a precursor of $\text{tRNA}_{1^{\text{Tyr}}\text{su}_3^+}$ only. It contains all the fragments observed in Altman's *in vivo* $\text{tRNA}_{1^{\text{Tyr}}\text{su}_3^+}$ precursor except the nucleotide pppGp representing the 5' terminus of the molecule. The fingerprint of the *in vitro* product contains in addition small amounts of pGp (spot 11) and a number of unidentified fragments (spots 6, 11–15, 22, 23, 25, 26) which were not observed in the *in vivo* $\text{tRNA}_{1^{\text{Tyr}}}$ precursor (Fig. 3c).

Transcription of λh80T DNA followed by S100 cleavage of the RNA (Fig. 2) was shown to produce in addition to band *e*, identified as $\text{tRNA}_{2^{\text{Tyr}}}$, band *f*, which is expected to contain the two tRNA species, tRNA_{Gly} and tRNA_{Thr} . Figure 2 shows that band *g*, present in the precursor even before the processing, behaves like a stable RNA species and migrates on the gel very close to band *f*. It was necessary therefore to repurify band *f* before the fingerprint analysis. The cut-out gel of band *f* was transplanted on top of a 16% acrylamide gel containing 7 M urea and was separated by electrophoresis from the faster running traces of band *g*. The fingerprint of band *f* (Fig. 3d), seems to contain the mixed sequences of both tRNA_{Gly} and tRNA_{Thr} .

* Fragment derived from tRNA_{Thr} (ref. 24).

† Fragment derived from tRNA_{Gly} (ref. 23).

In Table 2, the nearest-neighbour analysis of the different fragments from the fingerprint is compared with that expected for the respective *E. coli* tRNA species^{23,24}. The T_1 oligonucleotide $7^{\text{m}}\text{GUCCG}^{24}$ is absent from the fingerprint of the tRNA_{Thr} synthesised *in vitro*. Due to the presence of a non-modified G at the 5'-terminus, this fragment is degraded by T_1 to form UCG which appears as spot 7. Note that the pGp fragment, normally derived from the 5'-terminus of the tRNA_{Thr} and tRNA_{Gly} (refs 23 and 24) is absent from the fingerprint of the *in vitro* tRNAs synthesised *in vitro*. A tentative explanation for the absence of pGp at the 5'-terminus of *in vitro* tRNA_{Thr} and tRNA_{Gly} may be a wrong precursor cleavage by RNase P.

The RNA molecules migrating as band *g* (Fig. 2) were also

Fig. 4 Autoradiogram showing formation of tRNA from isolated precursor RNA. RNA bands were extracted from the gel separation of $\phi 80\text{psu}_3^{+/-}$ RNA or λh80T RNA synthesised *in vitro*, incubated for 60 min with S100 extract (10 min for band *a* from Fig. 1) and fractionated by polyacrylamide gel electrophoresis: 1, 2, 3, 4 and 5 refer to bands *a*, *b*, *x*, *c* and *d* from Fig. 1; 6 refers to band *a* from Fig. 2.

studied by the fingerprint method but did not seem to contain tRNA sequences.

Polycistronic tRNA precursors

Figure 1 suggests that RNA band *a* is a primary transcription product of the $\text{tRNA}_{1^{\text{Tyr}}}$ genes on $\phi 80\text{psu}_3^{+/-}$ DNA and that bands *b*, *x*, *c* and *d* are intermediate precursors of $\text{tRNA}_{1^{\text{Tyr}}}$. To provide further support for this assumption we have extracted the RNA bands from the gel and subjected them to cleavage by incubation with S100 extract. Figure 4 shows that a short incubation (10 min) of band *a* with S100 extract generates the intermediate RNA bands *b*, *x*, *c* and *d* as well as some $\text{tRNA}_{1^{\text{Tyr}}}$. RNA bands *b*, *x* and *c* all produce $\text{tRNA}_{1^{\text{Tyr}}}$ band on processing. Although band *d* RNA has been shown by fingerprint analysis (Fig. 3c) to carry $\text{tRNA}_{1^{\text{Tyr}}}$ sequences it was not cleaved after extraction from the gel and incubation with the S100 extract (Fig. 4). This behaviour is unexpected in view of the fact that this band does not seem to accumulate significantly when processing by S100 extract is carried out directly in the transcription mixture (legend to Fig. 1). The possible reasons for this observation are being investigated.

The isolation and cleavage of band *a* RNA from λh80T DNA transcript (Fig. 2) generates two RNA bands in the 4S region of the gel, one corresponding to $\text{tRNA}_{1^{\text{Tyr}}}$ and the other to the mixture tRNA_{Gly} , tRNA_{Thr} (Fig. 4, gel 6). It may therefore be concluded that the three tRNA species coded by λh80T DNA are present on a common polycistronic precursor. Polycistronic precursors for the tRNA gene clusters carried

by $\phi 80psu_3^{+/-}$ DNA and $\lambda h80T$ DNA have not yet been shown *in vivo*. The dicistronic RNA molecule containing tRNA^{Gly}, tRNA^{Thr} isolated by Carbon⁸ may be only a part of a primary precursor. The transcription *in vitro* of the adjacent genes of tRNA^{Trp}, tRNA^{Gly}, tRNA^{Thr} and tRNA^{Trp} (su_3^+ and su_3^-) as polycistronic precursors provides direct evidence that these genes belong to a single transcriptional unit.

We thank Mr Y. Tichauer for assistance.

Is the evolution of insulin Darwinian or due to selectively neutral mutation?

T. L. Blundell & S. P. Wood

Laboratory of Biochemistry, School of Biological Sciences, University of Sussex, Falmer, Brighton, Sussex BN1 9QG, UK

A model for the evolution of insulin mainly in terms of adaptive processes is discussed. The model depends critically on the relationship of sequence changes to the three-dimensional structure and the role of various parts of this structure in the conversion of the proinsulin molecule to the active form, the storage of insulin, its transport to the site of action and its interaction with a receptor.

SEQUENCES of functionally equivalent proteins provide the best evidence for selectively neutral mutations. As the knowledge of proteins increases, however, more detailed attempts to discern the relative importance of adaptive and neutral mutations in evolution may become possible. In particular, the detailed study of the role of different amino acid residues in a class of proteins and the effects of sequence changes on their physical and physiological properties is an essential prerequisite to an assessment of arguments for and against neutral mutations^{1,2}. Three principal arguments are given in support of neutral mutations. Kimura³ suggested that the substitutional load due to the high rate of evolution would have been intolerable unless most of the mutations had been neutral in natural selection. The main argument of King and Jukes⁴ is based on the observation that the rates of evolution of individual proteins are uniform and the idea that most amino acid differences between species are functionally insignificant. This uniform rate and the apparent latitude for random genetic change at the molecular level is said to hold for cytochrome *c*, haemoglobin, histone and also for insulin with the exception of guinea pig and coypu insulins. Markussen⁵ has calculated evolutionary rates for insulins based on nucleotide differences and considered insulin evolution in terms of predominantly neutral mutation.

We feel that the above views result from an oversimplification of the meaning of 'functional insignificance' and depend on the use of average rates of change without sufficient regard to the location and chemical nature of

sequence changes. We wish to discuss a model for the evolution of insulin mainly in terms of adaptive processes. We do not exclude the possibility of some neutral change; rather we wish to provide an alternative explanation for the evolution of insulin and to caution conclusions made on the basis of uniform rates and changes that seem not to not affect function.

Insulin is a protein hormone produced and stored in the B cells of the islets of Langerhans of the pancreas. It is released into the circulation from membrane-limited intracellular storage granules in response to raised blood glucose levels and facilitates removal of glucose and other metabolites to the tissues. Insulin is synthesised as a single chain precursor—proinsulin. Within the storage granules, enzyme action removes a peptide about 30 residues long—the connecting peptide—leaving the active hormone. Most insulins comprise 51 amino acids, 21 in the A chain and 30 in the B chain. The chains are linked by two disulphide bonds. Insulin binds to specific receptor sites on the target cell surface but the details of how a biological response is initiated are not fully understood.

The amino acid sequences of 28 insulins (from the jawless hagfish through bony fishes such as cod and birds such as the turkey, to mammals) have been determined (Table 1) and these insulins are active in other test animals. The rate of amino acid substitution for most insulins has been in the order of 1×10^{-8} per locus per year (Paulings).

The three-dimensional structure of pork insulin has been described in detail by Hodgkin *et al.*^{7–9}. The biosynthesis of proinsulin¹⁰, the storage in the B cell granules^{11,12} and the receptor binding^{13–15} have been studied widely. Our views depend critically on the relation of sequence changes to the three-dimensional structure and the role of various parts of this structure in the different aspects of the physiology of insulin. In fact several characteristics of insulin may be of importance in determining fitness. These might include the correct folding of the newly synthesised proinsulin molecule and its conversion to an active form, the storage of insulin, its transport to the site of action and its interaction with a receptor. Most of these characteristics

will depend on the integrity of the three-dimensional structure, possibly on the quaternary structure and certainly on the solubility of insulin, its interaction with other proteins in the organism, its thermodynamic stability and its resistance to enzymatic degradation. All these aspects could act as restraints at various stages of evolution and changes in the anatomy and physiology of different animals may change these restraints. For instance, the observation¹⁶ that the location of the insulin-producing B cell has moved from the gut wall in tunicates to clusters of cells at the anterior end of the gut in Agnatha and further to the specialised organ, the pancreas, enclosing both endocrine and exocrine (especially proteolytic) functions in higher vertebrates may give us some clue to the changes that could have occurred in storage restraints on the insulin molecule.

For insulin we can now begin to define the above characteristics in terms of the tertiary structure and the amino acid sequences. In this discussion we include the unpublished results of X-ray and circular dichroism studies together with the biological properties of a number of different insulins of known sequence.

Structure and function

X-ray analysis shows that the pig insulin monomer has a well defined, globular three-dimensional structure with an hydrophobic core and two predominantly hydrophobic surfaces (Fig. 1). These surfaces are important for association of the insulin molecules first as a dimer and then in the presence of zinc to a hexamer. The surface of the hexamer contains most of the hydrophilic residues. The hexamer has the shape of a torus with two zinc atoms bound in the central, cylindrical channel (Fig. 2). The amino acids responsible for receptor binding and stimulation of a biological

response are located by studies of chemically modified and semi-synthetic insulins. The monomer is the active form; although receptor binding involves some of the hexamer surface it probably requires certain of the hydrophobic residues involved in dimerisation also (Fig. 1). Maintenance of the tertiary structure seems to be essential for receptor binding.

The connecting peptide of proinsulin links residues A1 and B30 (Fig. 1) which are only 10 Å apart although the peptide is about thirty amino acids long. The proinsulin molecules hexamerise¹⁷, thus the connecting peptide must lie on the hexamer surface. The role of the connecting peptide seems to be not only concerned with the folding of proinsulin to the correct tertiary structure but also to increase the solubility of the hexamer in the presence of high zinc concentrations¹⁸. When the connecting peptide is cleaved the insulin crystallises as granules; with the exception of some hystricomorph insulins and probably hagfish insulin, the granules contain zinc insulin hexamers. The role of the zinc insulin hexamers seems to be to provide a storage form which is thermodynamically stable and more resistant to enzymatic degradation than the unassociated form. The zinc-containing granules of different species are usually crystalline in appearance but electron microscopy shows that they have a varied morphology, symmetry and molecular packing^{11,12}. This variation in granule structure finds a parallel in the variation of crystal shapes and forms in the laboratory. It seems that the ease of crystallisation of zinc insulin hexamers may be a reflection of the granular structure found in the B cell, and the insulin that can form zinc insulin hexamers may have evolved as a stable storage form. The hexamers are probably unrelated to receptor binding. Thus it can be seen that there are many facets of

Fig. 1 View of the insulin monomer indicating how the surface may be described in terms of various areas involved in activation from the prohormone, binding to the receptor and self association.

Fig. 2 Formation of the zinc insulin hexamer.

adaptation in the insulin molecule, only one of which is receptor binding.

Sequences and structure

The sequences available indicate that all insulins might attain the tertiary structure found for pig insulin. The disulphide bridges and the hydrophobic core of the monomer are invariant. The residues which vary do not have the same location in different classes of animals. In the mammals, with the exception of the hystricomorphs, all insulins can form dimers and zinc insulin hexamers. The most highly variable residues are A8–A10 and B29 and B30. These residues are close together on the hexamer surface; they are not essential for formation of the zinc insulin hexamer, but they do affect its solubility and its

ability to crystallise. Pig insulin molecules pack in the crystals with contacts between two equivalent isoleucine A10 residues. In bovine insulin the A10 residues are valines. As a consequence the crystal packing of the hexamers is slightly different as is shown by a 2.3 Å difference electron density map. The faces of bovine insulin crystals grow at different rates from those of pig insulin crystals and thus the crystals have a rather different appearance (Fig. 3). Such changes of solubility and crystal form may affect granule formation; although the changes are only small they may reflect the differences in granules of different mammals and these may have functional significance. We cannot rule out the possibility that the nature of B30 is important to a species-specific proinsulin conversion enzyme, but it does seem that the changes at A8–A10 and at B30 found in mammals have little effect on the receptor binding.

Rats show polymorphism in their insulins, and rat insulin I is unique in that it contains a proline at B9, an otherwise invariant residue. The two rat insulins have similar biological activities. The rat I insulin, however, has a rather different dependence of its circular dichroism on zinc concentration (T.L.B., S.P.W., and A. Wollmer, unpublished). This indicates that the proline at B9 may decrease the association constant to zinc hexamers. Thus, this change at B9 may not be selectively neutral in terms of aggregation of insulin in the storage process, although it seems that given sufficient zinc, rat I like rat II insulin can crystallise as zinc hexamers. The packing relationships of the hexamers in crystals show very different symmetries for the two insulins. Rat I insulin crystals are rhombohedral whereas rat II insulin hexamers pack in a cubic lattice, space group $P4_332$ (Fig. 3). This cubic crystal form may be related to the unusually clear crystalline arrangement of some rat granules shown by electron microscopy.

For fishes the nature and location of the changes is different and certainly not random. The residues A8, A9 and A10 are very different from those found in mammals and the variation within fishes is much less. In particular A8, A9 and A10 are conserved in fishes as histidine-basic proline residues; in mammals they are smaller, non-basic and sometimes hydrophobic. In contrast to the mammals, residues A12–A15, A17 and B1–B3 are changed in fishes. Most also possess an extra B-chain residue at the amino terminus. These two groups of residues (especially B0, B1, A13, A14, A17) are not randomly distributed but are close together in the monomer and are clustered with equivalent residues when dimers aggregate to hexamers. The changes are complementary in that they still allow zinc hexamer formation. A single change of the kind observed in most of these locations would not favour hexamerisation. Although collectively these changes do not affect hexamer formation, they do affect the nature of the crystal packing and therefore perhaps granulation. In the laboratory cod insulin can be crystallised in conditions used to prepare pig insulin crystals but the crystal form is orthorhombic instead of rhombohedral, although the crystals also contain zinc insulin hexamers¹⁹. The sequence changes seen in the insulin of the jawless hagfish, however, do affect aggregation. In this case the zinc binding residue B10 is not histidine and the insulin does not form zinc insulin hexamers. The storage form must be radically different, although there may be some aggregation through non-polar surfaces²⁰. The hagfish insulin may resemble an ancestral insulin²¹ which was not subject to severe storage restraints and thus had not evolved the complex enzyme-resistant, storage mechanism typical of mammals.

The insulins of rodents from the suborder Hystricomorpha are different from the insulins discussed above as they do not show the uniform rate of evolution characteristic of the other insulins. The insulins of the guinea pig and coypu have changed at B10. The residue is no longer the zinc-binding histidine, but rather asparagine or gluta-

mine. Ultracentrifuge²² and circular dichroism²³ studies indicate that guinea pig insulin does not hexamerise in the presence of zinc. Examination of the changes in amino acid sequences of coypu and guinea pig insulins show that there are further changes related to this lack of association. Residues B14, B17 and B20 uniquely change in guinea pig and coypu insulins to larger and more hydrophilic residues. Residues B4 and A1 also change to radically different residues; they are larger and more basic. All of these residues are clustered together in the three-dimensional structure and make up the large surface which in other mammals is hydrophobic and involved in close contacts in the zinc insulin hexamer. The residue changes in the guinea pig and coypu are not only non-randomly located, they also make the surface more hydrophilic and thus the insulin molecule more thermodynamically stable in the absence of aggregation in aqueous environments. The relevance of this to storage is emphasised by the finding that guinea pig granules contain no zinc and do not have a crystalline appearance. Both guinea pig and coypu insulins also have changes in the B-chain carboxy terminus. In guinea pig insulin the change is at B22 (arginine to glutamic acid). B22 arginine is normally involved in an iron pair interaction with the carboxy terminus of the A chain. In bovine insulin, removal of the carboxy terminus by the action of carboxypeptidase destroys this stabilising ion pair; the tertiary structure is very disturbed and the insulin no longer dimerises. In a similar way, circular dichroism shows that guinea pig insulin has a changed tertiary structure and cannot dimerise²¹ (Fig. 4). Furthermore, guinea pig insulin has a very low biological activity, about 2% of that of bovine insulin in *in vitro* assays.

Evolution of insulins

These observations allow us to construct some hypotheses concerning the evolution of insulins. We will first consider guinea pig insulin. Let us suppose that there was a local shortage of zinc to the B cell in guinea pig ancestors. Insulin would not be aggregated with the same ease to zinc insulin hexamers. It would then be selectively advantageous to allow mutations which make the surface involved in aggregation to hexamers more hydrophilic to increase

Fig. 4 Far ultraviolet circular dichroism spectra of bovine(—) and guinea pig (·····) insulin showing considerable differences in solution conformation.

thermodynamic stability. Although thermodynamic stability is increased, however, the unaggregated insulin molecules are still more susceptible to enzymatic degradation than zinc hexamers. It is well established that zinc insulin hexamers are much more resistant to tryptic digestion than the less associated forms. Thus it may be that the change of the trypsin-sensitive arginine at B22 to glutamic acid is selectively advantageous in terms of stabilising the molecule

Fig. 3 Two Zn insulin crystals. a, Bovine; b, porcine; c, rat I; d, rat II.

to enzymatic degradation²². The changes, however, cause a change of tertiary structure, and this no doubt largely contributes to the decrease in binding affinity of the guinea pig insulin to adipocyte receptors. In fact it has been established that guinea pig insulin is less active even in guinea pigs compared with bovine insulin⁶. This implies that guinea pig insulin has evolved to maximise its stability in storage but this has been deleterious as far as receptor binding is concerned. We have to assume that the role of storage is as important to the fitness of the organism to survive as is the primary function, that of receptor binding and biological activity. In summary the arguments concerning the guinea pig insulin seem to implicate adaptive changes related not to receptor binding but rather to several other characteristics which are important to the physiological role of the insulin molecule. This is consistent with the high rate of acceptance of mutations in this and possibly some related species²⁴.

For other insulins the rate is less but uniform and this has been said to be evidence in favour of neutral mutations. Neutral mutations would be expected to occur randomly within certain areas of the molecule which are not affected by restraints. Our description of the location of the amino acid changes, however, has demonstrated that the location of accepted mutations has been distinctly different in different classes of animals. We have shown that these changes affect different physical properties such as three-dimensional structure, solubility, thermodynamic stability, resistance to enzymatic degradation, self-association and crystallisation to different extents. Furthermore, these changes will probably affect various aspects of the physiology such as activation of the proinsulin molecule, the nature of the storage of insulin in granules and its transport to the storage site and to the receptor apart from any effect on the receptor binding. It is therefore possible that they may also have been adaptive changes. Although the general nature of the insulin receptor binding has been retained during evolution, the nature of these other physiological restraints may have changed at different times. But how does this give rise to the apparent constant rate of amino acid substitution?

If there are a number of different restraints on the acceptance of mutations, a change of restraint will necessarily give rise to a noticeable change in the rate of acceptance in the following circumstances. First, if a change of restraint is very rare and occurs at only one or two points in evolution. Second, if changes in the insulin molecule are advantageous in terms of one characteristic but lead to a decrease in fitness in terms of other characteristics. Third, if by chance the restraints all changed in one phase of evolution due to changes in selective pressure on the organism as a whole. In the case of insulin, let us assume that adaptive changes dominate observed changes in evolution, but that the nature of the restraints has been different over different periods of time during evolution. This would be consistent with the several different locations of accepted mutations in insulins from different classes of animal. In the case of guinea pig insulin, the restraints are not independent in our model. Certain of the amino acid changes are involved in more than one aspect of function. Inability to bind zinc affects thermodynamic stability, susceptibility to enzymatic degradation and receptor binding of the insulin. Thus the restraints are interdependent and further mutations beneficially affecting each of these restraints become selectively advantageous. This gives rise to a cascade of evolutionary change.

In the other insulins we have no reason to suspect that changes which are adaptive in terms of one characteristic have serious consequences for other aspects of the physiology of insulin. Thus a change in the residues affecting crystallisation may be advantageous in terms of stability of the granules or the rate that they are dissolved in the circula-

tion, but it may not seriously affect the rate of activation of the proinsulin molecule, the receptor binding or thermodynamic stability. Thus the changes in restraint do not usually lead to a cascade effect, and they may be considered as independent variables. If the changes of restraint are frequent in evolution but independent, there is no reason why we should observe a sudden change in the rate of evolution. Statistically it is not unlikely that the changes of restraints (if there are a large enough number of them) will give rise to a fairly uniform rate of change in amino acid sequence, although more detailed examination of the changes would reveal their location in the protein not to be random. This is what is observed for most insulins.

This argument assumes that the total pressure on the molecule at any one time is roughly constant. This at first seems to be an unlikely assumption. But, if the restraint changes which give rise to adaptive mutations do not directly relate to major aspects of the physiology of the animals, then this assumption seems more reasonable. For instance, changes in the solubility of the granules and the stability of the insulin molecules in circulation may be related to rather sophisticated changes in the speed of response to insulin and to the time during which an insulin molecule is active before it is degraded and removed from the system. Changes of this nature in quite closely related species are not unreasonable and may increase the fitness of the animal to its environment. Furthermore, some adaptive changes may occur to eliminate undesirable situations such as chance interaction of the insulin molecule with other proteins within the cell and during circulation.

In the insulin molecule we have seen that the receptor binding is a fairly constant restraint during evolution, and this has led to an invariance of some surface residues and those residues in the hydrophobic core which are responsible for the general tertiary structure and consequently the proper arrangement of the residues binding the receptor. The number, nature and relative importance of restraints will differ from protein to protein and so the average rate of acceptance of mutation would be expected to vary although in many cases it might be relatively constant within a group of functionally equivalent proteins. For instance, in the proinsulin-connecting peptide most residues must be on the surface of the proinsulin molecule and therefore they will be more susceptible to variations in the environment of the protein. The connecting peptide must also accommodate changes in the insulin molecule whose surface it covers. It is therefore plausible that the characteristics which act as restraints on the acceptance of mutations change more frequently for the connecting peptide. This is consistent with the higher rate of change of this peptide than for the insulin molecule as a whole.

In conclusion, it seems that in rare cases an amino acid may be changed in a way that is advantageous to one characteristic but deleterious to others. The functional characteristics are interdependent and the rate of evolution will undergo a sudden burst. A uniform rate for most proteins is, however, not unexpected if the functional restraints are independent in terms of the amino acids which are affected. A uniform rate of evolution and the observation that amino acid changes are functionally insignificant with respect to one characteristic do not seem to be conclusive arguments for attributing most sequence variation observed in proteins to selectively neutral or non-Darwinian evolution.

We thank Professors John Maynard Smith and Sydney Shall, and Drs Norman Lazarus, Michael Wallis and John Jenkins for helpful discussions and comments.

letters to nature

Precession in transient X-ray sources

THE origin of both the relatively long period and the transient nature of the recently discovered X-ray sources Ariel 1118-61 (ref. 1) and Ariel 0535+26 (ref. 2), with pulse periods of about 405 and 104 s, respectively, and decay times of days, is unclear. The pulse rate of A1118-61 has been attributed to an extremely short binary star orbital period³, or to an extremely long neutron star rotation period⁴. The quasi-sinusoidal nature of both X-ray light curves, unlike the sharply pulsed flux from Her X-1 and Cen X-3, would seem difficult to account for in a rotation model. The 104-s period, on the other hand, seems embarrassingly short for a binary orbital period. Therefore, I reiterate here an earlier suggestion⁵ that free precession may be important in such galactic X-ray sources. Such precession, which provides a plausible explanation for the 35-d quasi-sinusoidal period and intensity variation of Her X-1 (which has a 1.25-s pulse period) could directly account for the shape of the light curves of the transient X-ray sources.

If, as has been suggested, the initial X-ray outburst is triggered by the close approach of a neutron star (or white dwarf) to its main sequence companion, either because the collapsed star is moving in a highly elliptical orbit⁶, or because the radius of the companion is variable⁷, the accompanying rapid mass transfer might well provide the torque necessary to excite free precession of large amplitude in the collapsed object. For a neutron star of mass M , surface radius R , Alfvén surface radius r and total mass accreted m , the spin axis could change direction by an angle $\theta = mr^2/MR^2$ during a single encounter. The superposition of the effect of many mass transfer events (even if it is stochastic) could easily lead to a precession angle of large amplitude ($\theta \approx 10$ - 100°), since the damping times can be long (for example, greater than 10^6 yr for neutron stars⁸).

For a star spinning with a period T_s , and having matter density ρ , the free precession period T_f is roughly $T_f \approx \alpha T_s^3 G \rho$, where α is a numerical coefficient of order unity which depends on the detailed structure of the collapsed object (density distribution, rigidity, and so on). Identifying the observed periods of a few hundred seconds with the free precession period of a neutron star ($\rho \approx 2 \times 10^{14}$ g cm⁻³) and taking $1 \gtrsim \alpha \gtrsim 10^{-2}$, one finds $T_s \approx 0.1$ - 0.01 s. This range of spin periods is plausible, encompassing as it does the periods of three known pulsars (the Crab, binary and Vela pulsars with pulse periods of 0.033, 0.059, and 0.089 s, respectively). Such a high spin rate need not suppress matter accretion from a disk, provided that the magnetic fields of the neutron stars are somewhat smaller than the usually assumed value of 10^{12} gauss. The discovery of regular short-period pulsations

or amplitude variations in the X-ray flux from these transient sources would offer strong support for the present suggestion; its absence, although difficult to reconcile with most plausible beam profiles, is not decisive.

White dwarf X-ray sources, with spin periods of order 100 s, on the other hand, could also show evidence of free precession, but with a period of days. One might expect such a period to show up in the mean (averaged) intensity variation over an observation period of weeks. (I note that at least one white dwarf showing circular polarisation and thus probably having a strong surface magnetic field, G195-19, shows regularly periodic variations in polarisation with a period of 1.33 d (ref. 9), a period the discoverers attribute to rotation but which could well be the free precession period arising from a spin period of about 100 s.) In the present context, the discovery of either short (0.1-s) or long (1-d) periods in any of these X-ray sources could distinguish between models involving white dwarfs and those involving neutron stars.

I thank Professor P. Morrison for discussions. This work was supported in part by the US National Science Foundation.

Possible cosmological origin of spontaneous symmetry breaking

POPULAR unified theories of weak and electromagnetic interactions¹ are based on the notion of a spontaneously broken gauge symmetry. The hope has also been expressed by several authors that suitable generalisations of such theories may account for strong interactions as well. Here we propose that the spontaneous breakdown of gauge symmetries may have a cosmological origin. As a consequence we find that at some early stage of development of an expanding universe, a phase transition takes place. Before the phase transition, weak and

Fig. 1 Vacuum expectation value of the Higgs field plotted against the expansion parameter of a "standard" universe.

electromagnetic interactions (and perhaps strong interactions too) are of comparable strengths. The presently observed differences in the strengths of the various interactions develop only after the phase transition takes place.

In order to illustrate our ideas, we consider a 'proto-type gauge theory' of the Salam-Ward-Weinberg variety (with gauge group $SU(2)_{\text{LEFT}} \otimes U(1)_{\text{RIGHT}}$) in a curved space with prescribed metric tensor $g_{\mu\nu}(x)$. The action functional of the theory may be written as $W = W_0 + W_H$, where W_0 stands for the gauge-invariant action of massless Fermion fields and of the gauge fields. The form of W_0 is well known in flat space-time¹ and it is a trivial exercise to generalise that expression to a space of any given metric tensor $g_{\mu\nu}$. The action W_0 is automatically invariant under (infinitesimal) Weyl transformations, $\delta g_{\mu\nu}(x) = 2\Lambda(x)g_{\mu\nu}(x)$, $\Lambda(x)$ being an arbitrary smooth function. Likewise, the action of the isodoublet Higgs field, W_H , can be written in a form which is invariant under Weyl transformations^{2,3}:

$$W_H = \int d^4x \sqrt{(-g)} \left\{ -\frac{1}{2} g^{\mu\nu} \Phi^\dagger \left(\partial_\mu + i \frac{g'}{2} B_\mu + i \frac{g}{2} \tau A_\mu \right) \Phi \right. \\ \left. \times \left(\partial_\nu - i \frac{g'}{2} B_\nu - i \frac{g}{2} \tau A_\nu \right) \Phi - \frac{1}{12} R(\Phi^\dagger \Phi) - \frac{\lambda}{24} (\Phi^\dagger \Phi)^2 \right\} \quad (1)$$

Unless stated otherwise, we follow the notation of ref. 1 with obvious modifications to accommodate an arbitrary space-time metric. The quantity R stands for the Ricci scalar, $R = g^{\mu\nu} R_{\mu\nu}$. So Weyl (conformal) invariance can be broken only by the properties of the "cosmic background". In this approximation, our model is consistent with Mach's principle.

We assume that the metric is of a Robertson-Walker form,

$$ds^2 = dt^2 - a(t)^2 [(1-r^2)^{-1} dr^2 + r^2 d\Omega^2]$$

corresponding to a "standard" cosmology⁴, t being the "cosmic time", and so $a(t)$ is the radius of the universe. Units are chosen such that $\hbar = c = L = 1$ where L stands for the Planck length. We re-emphasise: the influence of the matter fields on the metric is neglected in this model. This implies that the energy-momentum tensor of matter can be written as $T_{\mu\nu} = p g_{\mu\nu} + (p + \rho) u_\mu u_\nu$, where p, ρ, u_μ are the classical pressure, mass-energy density and four-velocity, respectively.

Spontaneous symmetry breaking develops if the vacuum expectation value (VEV) of the neutral Higgs field, $\phi = \frac{1}{2} \times (1 - \tau_3) \langle \Phi \rangle$ differs from zero. In analogy with the flat-space case, ϕ satisfies the equation $(\square + (R/6))\phi + (\phi^3 \lambda/6) = 0$. To qualify as the VEV of a quantised field, ϕ can at most depend

on the cosmic time, t . Using the classical equations of the standard cosmology, $da = [(8\pi a^2/3) - 1]^{1/2} dt$, one introduces the expansion parameter $x = a(t)/a_{\text{max}}$ as an independent variable. The dimensionless parameter λ can be 'scaled out' by introducing the function $g = (\lambda a_{\text{max}}^2)^{1/2} \phi$. In the spirit of the standard cosmology, we assume that for $x \leq x_0$ the "matter" distribution is extremely relativistic ($p = (\rho/3) \approx 0$), while for $x \geq x_0$ the distribution is "pressureless", $p \approx 0$, $\rho \approx x^{-3}$. Thus, x_0 stands for the expansion parameter at which the "big bang" universe cools down sufficiently so as to become a "quiet" universe following a "fireball" stage. The value of x_0 is generally estimated to lie between the limits $10^{-6} \leq x_0 \leq 10^{-3}$, whereas the "present" value of x is approximately $x_1 \approx 0.69$. Corresponding to $p = \rho/3 \approx 0$ ($x < x_0$), and $p \approx 0, \rho \approx x^{-3}$ ($x > x_0$), we deduce,

$$\left(\frac{1-x^2}{x^2} \right)^{1/2} \frac{d}{dx} \left[x^3 \left(\frac{1-x^2}{x^2} \right)^{1/2} \frac{dg}{dx} \right] + \frac{x^3}{6} g^3 = 0 \quad (x < x_0)$$

$$\left(\frac{1-x}{x} \right)^{1/2} \frac{d}{dx} \left[x^3 \left(\frac{1-x}{x} \right)^{1/2} \frac{dg}{dx} \right] - \frac{1}{2} g + \frac{x^3}{6} g^3 = 0 \quad (x > x_0) \quad (2)$$

since, as a consequence of the Einstein equations, $R = (p - (\rho/3))$. The vacuum energy of the Higgs field is minimised by the trivial solution, $g = \phi = 0$ for $x < x_0$. In order to find the stable vacuum for $x > x_0$, we notice that by introducing the variable $y = (1-x)^{1/2}$ equation (2) for $x \approx 1$ (near maximal expansion) becomes

$$\frac{d^2 g(y)}{dy^2} - 2[g(y) - \frac{1}{3} g(y)^3] = 0 \quad (3)$$

In analogy with the flat space case, the stable solution of equation (3) is found to be $|g| \approx \sqrt{3}$ ($y \approx 0$). Thus, the VEV of the neutral Higgs field is zero as long as the universe is "hot" ($x < x_0$) and then it grows gradually to the limiting value, $\phi_{\text{max}} = (\lambda a_{\text{max}}^2/3)^{-1/2}$ as the universe cools down ($x > x_0$). In this model, the value of λ can be adjusted to reproduce the presently observed ratio of weak and electromagnetic couplings.

Equation (2) can be integrated numerically for $x > x_0$. A typical solution (with $x_0 = 10^{-4}$) is plotted in Fig. 1. We found that the solution for $x \geq 10^{-2}$ is very insensitive to the choice of x_0 within the above mentioned interval. Since $x_0 \ll 1$, the behaviour of $g(x)$ near x_0 can be estimated on the basis of the asymptotic solution near zero. There one finds $g(x) \sim x^\beta$ ($x \rightarrow 0^+$), $\beta = (\sqrt{17} - 3)/4 \approx 0.28$. Thus we approximate $\phi(x) \approx (x - x_0)^\beta$ near x_0 ; this behaviour is borne out by the numerical solution. Together with the relation between temperature and expansion parameter, $T x^2 \approx \text{constant}$, we thus estimate the critical exponent of ϕ to be $\beta \approx 0.28$ with a critical temperature $T_c \gtrsim 10^5$ K.

Since the effective weak interaction constant, G_F , is proportional¹ to ϕ^{-2} , its value changes very little during the present age: $\dot{G}_F/G_F = -2 \dot{x} \log g / dx \lesssim -10^{-10} \text{ yr}^{-1}$. But it is remarkable that according to this model, weak and electromagnetic interactions were of comparable strength (and of long range) within the primordial fireball. The consequences of this result (particularly with regard to a neutrino background) are at present under investigation.

We thank B. I. Dunlap for advice concerning the numerical solution of equation (2).

A Megalithic observatory on Dartmoor

ASTRONOMICALLY aligned standing stones have been shown to occur at many sites dating from the late Neolithic and early Bronze Ages in North-west Europe. We have examined the stone rows at Merrivale on Dartmoor (SX553746) and conclude that they, together with associated stone rings and menhirs, form a solar and lunar observatory. An interesting feature of this site is that it apparently includes a calculating device for facilitating the prediction of lunar eclipses. Thom^{1,2} has suggested that certain stone settings which are themselves not astronomical alignments, notably four fan-shaped arrangements of stones in Caithness (Mid Clyth, Dirlot, Loch of Yarrows and Camster) and the well known groups at Carnac and Kermario, are in fact for this purpose. The Carnac alignments are complicated and difficult to interpret completely, the Caithness settings have been disturbed and many stones are missing; at Merrivale the stone rows have not been greatly damaged and the simple method of their use, though not identical to that proposed by Thom, lends support to his basic contention that techniques for lunar eclipse prediction were developed at that period.

Fig. 1 The stone row site at Merrivale, Dartmoor.

We do not describe the Merrivale site in detail here, as it is hoped to publish a full account elsewhere. The stone rows (Fig. 1) lie on the summit of a fairly flat-topped bluff, which is covered with typical moorland vegetation of rough grass on peat and is, for the most part, free from boulders. There are two double rows, both roughly east-west; Row AB, 181.7 m long on an orientation of 83.7°, has 91 stones in its northern line, and 95 in its southern, most occurring in equally spaced pairs. Row CE has a length of 263.7 m, and is on an orientation of 81.7°. We found, with probing, 136 stones in the northern line and 130 in the southern. Neither double row is exactly straight, deviating about 2 m from the straight line, nor has a constant separation between the rows, which varies irregularly from 0.6 to 1.2 m. Both these rows have pairs of large stones to mark their western ends and a single stone set transversely to the rows at their eastern ends. Row AB has smaller stones than Row CE on average, but they are more uniformly spaced, with an average spacing of 1.86 m, whereas in Row CE the spacing changes from 2.05 m at the western end to 1.12 m at the eastern.

Row CE has a small egg-shaped ring, D, at about its mid point surrounding a cairn. Both rows have occasional large stones, (V, W, X, S, T, U, O, P, Q, R) along their lines, which stand about a metre high, compared with an average height of less than 0.5 m for the rest.

A third row of single stones, FZ 42.3 m, is at an angle of 57° to Row CE. The end of the row begins on the top of a small cairn and its first stone, F, is set with its broad face across the line of the row, as is the final stone Z. Very few stones are visible above the peat, and these are only about 0.1 m high. The row was probed and the peat was lifted to confirm the existence of possible stones. This row appears to be virtually complete, and there are 41 stones with a mean interval of 0.98 m. Apart from F and Z, none of the stones could have been more than 0.25 m above ground level, even in the Early Bronze Age, before the peat accumulation started.

About 100 m south of the rows is a well preserved ring H, of eleven stones (flattened circle, Thom Type B) and about 50 m north-west of A there is a true stone circle, J. The site also has several cairns, kists and four menhirs.

The site was surveyed by Lukis³ in 1879 and again by Worth⁴ who has also described some of its features⁵. During the investigation the site was resurveyed by sighting on the corners of three buildings whose 10-figure grid references were supplied by the Ordnance Survey Archaeological Division.

The north-west horizon, about 1.6 km from the site, is a smooth undulating moor with an elevation between 2.5° and 3.5°, broken by three separate outcrops of granite. Two of these outcrops make distinctive notches on the horizon. One of these, when viewed from the centre of ring H would have indicated the position of midsummer sunset (declination ϵ) in late Neolithic times, a second notch could have marked the position of the Moon, setting with declination $\epsilon + i$ (where i is the inclination of the Moon's orbit to the ecliptic) when viewed from the centre of J (Fig. 2).

We have been unable to find any outliers to the two stone circles which explicitly indicate these distant foresights. But two stone slabs in the centre of the site indicate the notch L on Fig. 2 and an outlier to the "egg" at D indicates notch M.

Although the horizon in other directions has prominent features, none of these is in a position to enable astronomical alignments to be made in other quadrants. Furthermore, the rows themselves are not aligned with astronomical significance.

For the present purposes the Moon's movements in declination may be regarded as a sinusoidal oscillation of amplitude ϵ and period 27.32 d, sinusoidally modulated by an oscillation of amplitude i and period equal to the rotation of the lunar nodes, 18.61 yr, and a minor perturbation, Δ , of amplitude 0.15° and period equal to half an eclipse year, that is 173.3 d. Whenever Δ is a maximum, the moon is at an "eclipse danger period". Thom points out that if Megalithic astronomers could make measurements that were accurate enough to observe the minor perturbations, they would be in a position to predict the possibility of lunar eclipses⁶. In essence this can be done by moving one's observation position from moonset to moonset, so that it seems always to set behind a suitable distant notch. Markers on the ground would effectively indicate a scale of declination measurement.

We propose the stone rows at Merrivale were used in this way, and that their purpose is to provide a permanent scale of measurement. The suggested method of use is that the observer moved, at each lunar setting, to that position along the double rows where he would see the Moon set in exactly the same place behind notch M. He could then place a temporary marker between the stone rows to indicate where he stood, and markers placed at successive moonsets would readily reveal the day on which the Moon had set with maximum declination, because on that occasion the markers would be nearest to the western ends of the double rows. The small deviations of the stone rows from straight lines would not materially affect the results. The rows are of such a length as to cover a lunar declination range of 26.0° to 30.1°, which means that they could have been used

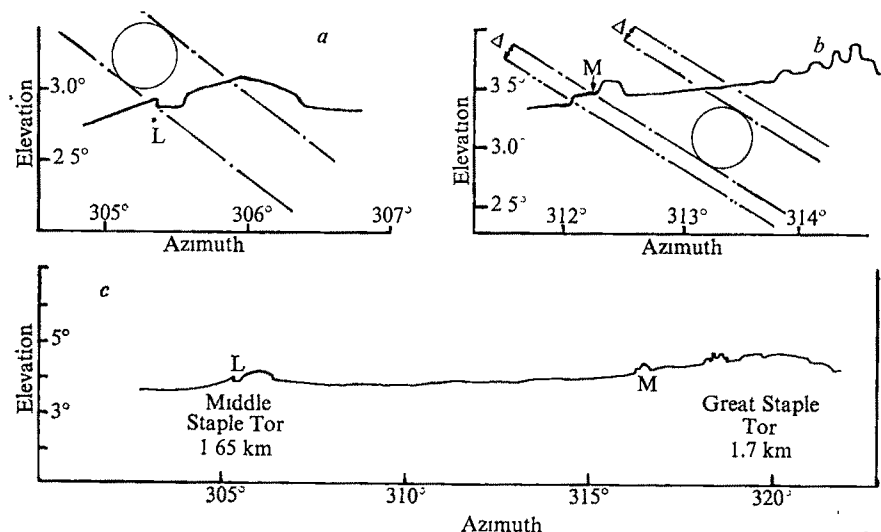

Fig. 2 *a*, The path of the setting Sun as seen from the centre of stone ring H in 2500 BC; *b*, the path of the setting Moon as seen from the centre of the stone circle J in 2500 BC; *c*, the north-west horizon as seen from the stone ring at Merrivale.

for about two years on either side of the declination maximum in the 18.61-yr cycle.

To achieve sufficient accuracy, the method needs to be elaborated, because the Moon may not be at its maximum monthly declination at the hour when it sets, and relatively small departures from the maximum would obscure the minor perturbation. Thom suggested a method by which the true monthly maximum declination could be obtained geometrically from the positions of markers placed on two successive nights. He shows that if the two markers nearest to the declination maximum are spaced a distance apart, $2p$, one must extrapolate a distance $G - p + (p^2/4G)$ from the further marker to find the position where one would have stood, if the Moon had set with maximum declination for the month⁷. G is a constant for the site; it is the ground equivalent to half a day's change in declination from the maximum, and its value could have been found empirically by the prehistoric astronomers.

Thom's method involves the fan-shaped stone settings referred to earlier, and gives a precise value for the extrapolation distance $G - p + (p^2/4G)$, but our method is to approximate the parabola given by Thom's expression by the arc of a circle.

Fig. 3 The curve LRM represents the extrapolation distance $G - p + (p^2/4G)$ as a function of p . It is approximated by the arc of a circle centred at N with radius $NM = 2\frac{1}{2}G$. Scales in units of G .

Thus on Fig. 3 a circle centred at N with radius $2\frac{1}{2}G$ very closely matches the parabola LRM. If this construction were to be laid out on the ground, then to find the required extrapolation distance, one would lay off a distance MQ equal to half the marker separation, and the perpendicular, QR, from the baseline to the arc would be the extrapolation. This geometric construction is not the only solution; the same extrapolation distance is obtained if the circle has a radius of $8\frac{1}{2}G$ and the whole of the distance between the markers is laid off along MO. In general, if a fraction r of the marker separation is laid off, the correct value for the radius of the circle is $\frac{1}{2}(1+16r^2)G$. This method of extrapolation appears to have been followed at Merrivale using the short stone row FZ.

Fig. 4 The method of extrapolation at Merrivale. Lay off a distance FF_1 equal to $\frac{1}{2}\sqrt{2}$ of the marker separation; the extrapolation distance is the perpendicular F_1F_2 to the circle radius $5G$ centred at C. This gives a more accurate extrapolation than by laying off YY_1 equal to $\frac{1}{2}$ of the marker separation.

The Merrivale site has many interesting geometrical properties, including the repetition of certain units of length in its construction. One of these units is 15.6 m, which occurs as multiples along row CE in the spacings between the large stones. Thus we find (to within 1%) $OQ = 1$, $QR = 3$, $OR = 4$, $CU = 8$ and $UE = 9$ units. We are inclined to equate the unit of 15.6 m with Thom's constant G , which is calculated, using Heggie's method⁸, to have a mean value of 15.3 m over the site. The rows incorporate a triangle CZY (Fig. 4) in which ZY is the perpendicular to CZ, and if our interpretation is correct, two sides of the triangle, CZ (78.2 m) and ZY (45.6 m) are close to $5G$ and $3G$ respectively. This triangle ($r = \frac{3}{5}$) would therefore be one of the

family that could be used for extrapolation. The method would be to measure the distance between markers on successive evenings, lay off three-quarters of this distance from Y to Y_1 , and then project the perpendicular Y_1Y_2 to meet the circle centred at C. The length of this perpendicular is the distance to be added westwards from the further marker to get the position that the marker would have indicated, if the Moon had set with its monthly declination maximum.

In fact the short stone row FZ is not quite perpendicular to CZ and its length is 2.71G, not 3G. This slight modification to the simple scheme reduces the error inherent in this method of extrapolation, due to approximating the parabola with an arc of a circle, by about a factor of four and to a magnitude where it is insignificant. The distance to be laid out along FZ is not now $\frac{3}{4}$ of the marker separation, but $\frac{1}{2}\sqrt{2}$ which can easily be obtained by a simple geometrical construction using strings and pegs.

In examining prehistoric sites from an astronomical viewpoint one must guard against introducing fortuitous alignments or selective analysis of data. Thus one test for validity is the accuracy of the demonstrated alignments. Some authors, notably Thom, have taken great trouble with their surveys to find the exact declination of the Sun or Moon for the observing lines. In the present case it is difficult to apply this type of test, since the hypothesis is that the observers moved along the stone rows until they were observing the moonset exactly behind a particular distant feature. A test that can be applied is whether the hypothesis plausibly, and preferably quantitatively, explains the archaeological remains. The hypothesis advanced in this letter gives an explanation for the existence of the stone rows at Merrivale, including the precise dimensions and siting of the short single row, but there are many features of the site which we are unable to explain, of which the most obvious is why there are two double rows. For one apparently duplicates the function of the other. We have not examined any other site on Dartmoor.

We thank Mr A. H. Wood for help.

Palaeozoic secular variation recorded in Pendleside Limestone

RESULTS discussed here demonstrate the value of limestones in palaeomagnetic work. The fact that these rocks can apparently record secular variation provides evidence that the magnetisation is of depositional or very early diagenetic origin. Limestones may become a valuable tool in studying the ancient geomagnetic field.

Records of long term variations in the Earth's magnetic field over the past 15,000 yr or so come from lake sediments¹, marine sediments², archaeological materials³ and also from observatory records covering the past few hundred years.

Fig. 1 The natural remanent magnetisation of two hand samples of Pendleside Limestone after a.c. cleaning at 150 oersted. Continuous curve is the mean of three curves obtained by slicing the cores into 1-cm disks. The error bars show the range of variation at each level.

Secular variations have also been convincingly demonstrated in Tertiary lavas⁴ and Mesozoic and Tertiary sediments. An important feature of secular variation is its strong dependence on latitude. Analyses of Recent geomagnetic data^{5,6} show that along lines of latitude progressively nearer the Equator, geomagnetic field directions become progressively more dispersed. Thus, the magnitude of secular variation should be greater nearer to the Equator. Tarling⁷, using the 1965 field data found a circular standard deviation ranging from about 7° near the poles to 19° near the Equator.

Although there have so far been no convincing records of Palaeozoic secular variation (before 225 Myr BP) variations could be preserved in certain Lower Carboniferous (Viséan) limestones⁸. The available evidence suggests that the magnetisation of these limestones, which is highly stable and easily measurable, was acquired during or very shortly after deposition.⁹

To test this hypothesis a large palaeomagnetic collection of over 50 sites (including a few hand samples) has been made. None of the results from the collection has been discounted and all will be reported elsewhere. Results from two hand samples (44 specimens) are presented here as they provide a convincing demonstration of secular variation in Palaeozoic limestones. The sampled section is in the upper part of the Worston Shale Group and the Pendleside Limestone at Salterforth railway cutting (OS Ref. SD 889459) in northern England. It consists of alternating dark, fine grained limestones and shales. The two hand samples discussed here were collected from different horizons 11 m apart in the Pendleside Limestone. Three cores were drilled perpendicular to the bedding plane in each sample and then sliced into seven or eight 1-cm disks which were measured using a Digico magnetometer. The disks were then cleaned in an a.c. field of 150 oersted and remeasured

(Fig. 1). Several factors suggest that the results record Carboniferous secular variation.

- The variation in declination and inclination approximates to a sine wave and is quite regular. The amplitude of the variations is comparable with other secular variation records. In view of the low palaeolatitude of the Pendleside Limestone (15°) it may be expected that the amplitude of the variations should be greater. There are, however, two reasons why the amplitude of the variations is anomalously low. In the first place, the Carboniferous geomagnetic field may have been much steadier than the Recent field. In the second place, and this seems much more likely, the smoothing may have been brought about by each specimen acquiring its magnetisation over a long period of time. Only if the magnetisation were acquired penecontemporaneously would the full amplitude of the secular variation cycle be preserved. The degree of smoothing shown by the curves shows that the magnetisation of each specimen partly represents an integration of contemporary geomagnetic fluctuations. This supports the contention that the magnetisation of the limestones is of early diagenetic origin⁹.

- The periodicity of the variation in declination is compatible with Recent records, assuming a sedimentation rate of 1 cm every 500 yr; such a sedimentation rate is quite consistent with our present knowledge of marine carbonate sedimentation rates.

- The validity of the variations is supported by the correlation between the three cores in each hand sample. Both declination and inclination plots are all in close agreement and only one measurement, in the declination of PL42 (Fig. 1), is slightly out of phase.

- Comparison between the declination and inclination curves indicates that the variation in inclination is less than that in declination (Fig. 1). This is generally the case for many secular variation records. Moreover, both curves show trends with two declination swings to one inclination swing. This is another feature common to many secular variation records.

- There is some agreement between inclination and intensity of magnetisation, such as may be expected were the variations really secular variations. Low-field susceptibility has been measured to check if the intensity variation is a function of magnetic mineral content. This is not the case because no variation in susceptibility (13.5 μ gauss oersted⁻¹) could be detected within or between cores.

Earliest calcareous foraminifera

WE present here evidence that early Palaeozoic calcareous foraminifera existed and were relatively complex (multilocular and multiserial) in form but that they have been regarded formerly as calcareous algae. The early part of the invertebrate fossil record during the Cambrian period seems to show a striking contrast between the abundance of highly developed organisms such as the trilobite arthropods and the paucity of simpler forms such as the foraminiferal protozoans. Foraminifera are very small acellular animals with an important role in marine food chains¹ and it is reasonable to expect

them to have been a significant component of the benthic fauna throughout the Palaeozoic. Yet few foraminifera have been reported from the Lower Palaeozoic and those described from the Cambrian are mainly simple forms with unmineralised tectinous or agglutinated tests^{2–4}. Some more complex agglutinated forms are known from the Upper Cambrian⁵, but the first generally recognised calcareous foraminifer is the uniserial *Saccaminopsis* from the late Ordovician⁴. Consequently, the assumptions that Lower Palaeozoic foraminifera were primitive and mainly non-calcareous have been taken as bases for inferences concerning the early evolution of the group^{3,4} and the paradoxical, yet apparently inescapable, conclusion has been drawn that Cambrian foraminifera are very scarce.

We describe here small, septate chambered organisms with a thick calcareous wall belonging to a generic group centred on *Renalcis* Vologdin, and termed here renalcids. At least six nominal genera are involved (*Renalcis*, *Nubecularites* Maslov, *Chabakovia* Vologdin, *Shuguria* Antropov, *Izhella* Antropov, *Nephelostroma* Dangeard and Doré) although only two, *Renalcis* and *Izhella*, are likely to prove acceptable. Renalcids range throughout the Cambrian and are also well known from the Lower Ordovician and Upper Devonian. *Renalcis* has also been found recently in the Silurian of Khazakhstan, USSR (I. T. Zhuravleva, personal communication). They have a global distribution and are locally very abundant in a variety of early and middle Palaeozoic bioherms constructed by stromatolites, archaeocyathids, sponges and stromatoporeoids⁶. Various affinities, some foraminiferal but mostly algal (Table 1), have been attributed to renalcids. The view that they are algae is not consistent with their morphology and a more satisfactory explanation is that they belong to the Palaeozoic foraminiferal superfamily Parathuramminacea⁷.

Renalcids have a microgranular calcareous wall and a septate chambered structure. An individual test can include from 2 to more than 80 chambers. Internal chamber sizes range from 10×40 to 200×250 μ m. Wall thickness ranges from 5–125 μ m. The chambers are connected by intercameral foramina in the septa (Fig. 1). Apertures seem to be lateral and there are no pores in the wall. The complete test is generally between 500 μ m and 1 mm in size. These dimensions are based on numerous measurements of Cambrian and Devonian specimens. Chambers are usually arranged in several branching series. In random thin sections these seem to arise from a cluster of small chambers (Fig. 1) or from a large initial chamber which may be the proloculus. The specimen shown in Fig. 1 is from the Devonian and has been selected for its good state of preservation, but closely comparable specimens have been figured from the Cambrian of Siberia⁸. Renalcids may occur free in fine-grained sediment or attached to larger skeletons⁹.

Attributions of algal affinity to renalcids have been conflicting and are difficult to support. Both blue-green and red algae have been referred to. Blue-green algae are either filamentous or coccoid in form. Calcified filamentous blue-greens produce non-septate tubiform skeletons ascribed to genera such as *Girvanella* and *Ortonella*⁹. These are much smaller and totally

different in morphology from renalcids. Calcified coccoid blue-greens are not known from the Recent but calcification of the mucilaginous sheath surrounding coccoid cells could also be expected to produce skeletons morphologically and dimensionally quite distinct from renalcids. It is inconceivable that the chambers of renalcids represent individual blue-green cells, as Maslov¹⁰ has suggested, since their sizes differ by an order of magnitude. Korde^{8,11} suggested that the renalcid wall has a minutely cellular structure which indicates an affinity with red algae. But the cellules she reported are orders of magnitude smaller than the cells of undoubted fossil and Recent calcareous red algae. Further, we have been unable to detect cellular microstructure in the walls of renalcids from a variety of geological situations. Rather, the tests seem to comprise finely granular calcite with no visible structure, an observation supported by scanning electron microscope (SEM) studies¹².

The size and morphology of renalcids are, however, consistent with their being foraminifera. The skeletons consist of chambers, connected by intercameral foramina and with lateral apertures, arranged in extended branching series. A foraminiferal affinity for renalcids has received some previous support^{13,14} (Table 1). Even so, uncertainty has remained concerning their precise position. Elias¹³ thought that *Chabakovia* was related to *Ptychocladia* and placed both in a new foraminiferal family, *Ptychocladidae*. Loeblich and Tappan⁴ placed this family in the Endothyraea, but tentatively removed *Chabakovia* to the problematic group Reitlingerellida. They placed *Shuguria* in the parathuramminacean family Caligellidae. In our opinion the rather irregular form, relative morphological simplicity, and finely granular unlayered calcareous wall favour the placement of the renalcids as a discrete group in the Parathuramminacea⁷.

We propose to name this family Renalcidae, defined as follows. Test free or attached, irregular, branching uniserially; chambers numerous, lunulate to hemispherical, early chambers inflated; wall thick, calcareous, microgranular; apertures lateral. Type-genus *Renalcis* Vologdin. The Renalcidae differ from other parathuramminacean families in having thick walls, closely compressed chambers, and a tendency to branch. They most closely resemble the Caligellidae but differ in having a well developed septation, more compact form, and a lack of well defined coiling at any stage. The *Ptychocladidae* are very similar to the Renalcidae in the form of their branched uniserial test, but differ in their prostrate and always attached habit, radial partitions in the larger chambers, and layered wall.

The foraminiferal nature of renalcids has significant bearing on the early history of the Foraminifera: calcareous stocks now seem to be as ancient as agglutinated stocks, provided

that dubious Proterozoic specimens⁵ are disregarded. *Renalcis jacuticus* is one of the first calcareous organisms to appear in the lowest stage of the Cambrian, and the underlying Precambrian Yudomian strata have yielded *Nubecularites abustus*¹⁶.

In the Baltic region the agglutinated foraminifer *Platysolenites antiquissimus* (homeomorphic with *Bathysiphon*) is, likewise, one of the first shelled organisms to appear in the sequence, occurring in the Precambrian Vendian strata¹⁷. The Vendian and Yudomian are of similar age¹⁸ and the detailed biostratigraphy is uncertain, so that it is hard to say precisely which stock, calcareous or agglutinated, is the older. Consequently, it is difficult to support the inference that all calcareous foraminifera arose from agglutinated stocks as suggested by Loeblich and Tappan¹⁹. Both seem more likely to have arisen independently from simple, late Precambrian, tectinous forms.

With the recognition of renalcids as foraminifera two Cambrian foraminiferal biofacies now become apparent. Agglutinated microfaunas (for example, *Scaniella*, *Platysolenites*, *Psammospaera*, and *Hippocrepina*) dwelt in predominantly argillaceous sediments, associated with hyolithids, hyolithellids, trilobites, brachiopods, and siliceous sponges²⁰. Conditions were probably turbid and cool^{17,20}. Calcareous microfaunas (renalcids) dwelt in predominantly calcareous sediments associated with archaeocyathids, trilobites, chancellorids, gastropods, and the alga *Epiphyton*. Conditions were probably warm, clear and shallow²⁰. Warm, shallow-marine, carbonate environments of Upper Palaeozoic–Recent age also contain abundant calcareous foraminiferal assemblages. If renalcids were lacking it would be difficult to explain why similar habitats were unoccupied by calcareous foraminifera in the Lower Palaeozoic, especially as conditions favoured many other shelled organisms, and other not entirely hospitable environments supported foraminiferal assemblages.

The basic features of the renalcid test may be explained ecologically. Warm, CaCO_3 -saturated waters favour the secretion of thick calcareous walls, whereas agglutination is favoured in cooler or less saturated waters²¹. Chambers and septa, formed by periodic growth, serve as physical and osmotic barriers for the protoplasm inside²². Protection of this kind is of value in shallow-water biohermal environments where temperature, water-movement, predation, and ultraviolet radiation are likely to be high and where plant respiration and photosynthesis may cause local fluctuations in pH and Eh. Chambers may also help to culture algal endosymbionts, an association commonly found in shallow-marine tropical foraminifera²³.

We conclude that renalcids were the earliest calcareous foraminifera and belong to the superfamily Parathuraminacea. Their presence in the early Cambrian suggests that calcareous foraminifera arose, independently of agglutinated foraminifera, from tectinuous forms. Renalcids were adapted to the warm, shallow-marine, biohermal carbonate environments found widely across the continental shelves in early Palaeozoic times.

Mechanism of oxidation of polyacrylonitrile fibres

THE first and most important stage of the preparation of high modulus carbon fibres from polyacrylonitrile (PAN) textile fibres is the oxidation of the fibres under tension. This produces an oxidised ladder polymer structure approximately parallel to the fibre axis which may be regarded as the template for the formation of the oriented carbon fibre. The exact structure of this oxidised polymer is not clear although four different ones have been proposed^{1–4}.

The structure of the unoxidised ladder polymer, which is formed without weight loss by heating PAN in a vacuum at temperatures of 180–230 °C is well established however, and, neglecting initiation points, is a condensed naphthyridine ring structure⁵:

Fig. 1 Oxidation with no previous treatment. The values for oxygen taken up are the total found by analysis less the value before oxidation. A, Fibre A; B, fibre B.

This structure confers a copper colour to the fibres heated in vacuum because of the conjugated $\text{C}=\text{N}-\text{C}=\text{N}-$ system.

Textile PAN fibres are copolymers of acrylonitrile with one or more comonomers which are added to provide dye sites and also, by introducing points of structural inhomogeneity, to act as internal plasticisers and make fibre drawing easier. The various proprietary PAN fibres have different comonomers in them, a common quantity being about 6% by weight. It has not yet been shown, however, what effect these different comonomers have on the oxidation kinetics of PAN fibres. In this communication we compare the oxidation kinetics of two commercially available PAN fibres.

Fibre A was a round wet-spun fibre of 1.5 denier (cross-sectional area $133 \mu\text{m}^2$) of composition 95.0, 4.6 and 0.4 mol % of acrylonitrile, methyl acrylate, and a vinyl acidic compound providing COOH groups directly attached to the all-carbon polymer chain. Fibre B was dry spun with a 'dog-bone' cross section of 1.8 denier (cross-sectional area $165 \mu\text{m}^2$) and of composition 95.4 and 4.6 mol % of acrylonitrile and methyl acrylate, respectively.

The oxidation of the fibres was investigated by estimation of the oxygen absorbed after different oxidation times at 230 °C in air with the fibres tied on a glass frame and by examination with an optical microscope of cross sections of oxidised fibres cut to $1 \mu\text{m}$ thickness on an LKB microtome. The oxygen absorbed is shown in Fig. 1 and the cross sections of the fibres after 4 h of oxidation are shown in Fig. 2A and B. Fibre A has a fast initial oxidation rate and the sections showed what we have previously called an oxidation zone⁶ inasmuch as it moves inwards at a rate proportional to the square root of the oxidation time. Fibre B has a slow initial rate which increases with time, but at 230 °C does not show any oxidation zone, at least up to times of 4 h. The colour gradually changes uniformly over the section to a mid-brown.

As-received fibres were heat treated in a vacuum for 6 h at 230 °C, again while tied on glass frames. The weight changes were negligible but both groups of fibres were copper coloured, indicating extensive transformation into ladder polymer. The oxidation at 230 °C and microscopical examination of these fibres was carried out as before and results are shown in Fig. 2C and D and Fig. 3; the sections showed oxidation zones after only 1 h of oxidation. Clearly the vacuum heat treatment before oxidation has not changed the oxidation

Fig. 2 A, B, Cross sections of fibres A and B, respectively, after 4 h in air at 230 °C. C, D, Cross sections of fibres A and B, respectively after 6 h in vacuum at 230 °C and 1 h in air at 230 °C.

kinetics of fibre A but has had a marked effect on fibre B, so that the oxidation kinetics are now similar to those of fibre A.

It seems that it is ladder polymer which is oxidised and this must be formed first. The acidic constituent of fibre A acts as an initiator for ladder polymer by the following mechanism as shown by Grassie, and this occurs rapidly at 230 °C:

Fibre B, with no acidic constituent, does not initiate ladder polymer formation very readily and this explains the different oxidation curves before and after the heat treatment. The presence of oxidation zones in fibre A, with or without heat treatment, shows that the rate of oxidation of the ladder polymer is faster than the rate of diffusion of oxygen in the fibre at 230 °C, whereas in untreated fibre B the rate of formation of ladder polymer and thus the rate of oxidation, is slower and cannot keep up with the rate of diffusion at 230 °C so that no oxidation zones can be seen unless the fibre is vacuum heat treated first. The conclusion drawn from these results, that formation of ladder polymer is a prerequisite to oxidation, is consistent with the structural formula for the oxidised ladder proposed by Potter and Scott⁴, based on the susceptibility to air oxidation of the ladder structure to give a pyridone structure. Three out of the four formulae proposed for the oxidised ladder polymer can, however, be reconciled if account is taken of oxidation mechanism and successive tautomeric changes, as follows:

Fig. 3 Oxidation after 6 h of vacuum treatment at 230 °C. ○, Fibre A; ●, fibre B.

The lengths (n) of the conjugated sequences are probably about 4–5 monomer units and the formulae proposed apply only to the oxidised ladder polymer. No account has been taken of some chain scission which does occur during oxidation, as shown by the evolution of CO_2 (presumably from $-\text{COOH}$ groups) in the early stages of the subsequent inert pyrolysis to carbon fibres. These can be formed by oxidation of the polymer ends resulting from the scission, and these $-\text{COOH}$ groups thus formed can then initiate chain scission⁷. This may be the mode of initiation with fibre B, thus accounting for the acceleration of the oxidation rate with time.

The technique of examination of thin sections of oxidised fibres seems to be a new and sensitive technique of assessing PAN fibre oxidation kinetics and is being followed up in more detail. It is more positive than the examination of polished cross sections which we have previously used to investigate the oxidation of 3 denier ($284 \mu\text{m}^2$) PAN fibres⁶.

Our assumption that the outer zone was oxidised PAN whereas the inner core was not has been verified using an electron microprobe analyser tuned for oxygen detection and comparing the oxygen level in the zone and core of an oxidised fibre. It was found that the brown outer zone is relatively rich in oxygen compared with the light yellow core⁸.

We thank R. Fennell and B. Cheeseman for the direct oxygen estimations using a Coleman oxygen analyser.

Artificially triggered lightning above land

LIGHTNING has been triggered artificially in the Massif Central by launching small rockets carrying a thin steel wire connected to the ground. During two investigations in 1973 and 1974, a total of 20 triggerings have been achieved. Photographic evidence establishes the existence of two kinds of luminous object, lasting several tenths of a second, which may be similar to some varieties of ball lightning.

A sudden perturbation of the electric field can trigger lightning^{1,2} and deliberate triggering of lightning with low cost equipment was first demonstrated by Newman *et al.*³, who launched small rockets carrying a thin wire connected to earth towards electrified clouds. The experiments were performed from a ship; our experiments extend this work to a fixed land-based station. Notwithstanding the lack of mobility, such a station does allow experiments that would be impossible or at least very difficult to perform at sea.

Our programme is the result of a joint effort by the Commissariat à l'Energie Atomique (CEA) and Electricité de France (EDF). The wire and rocket technique was developed initially at the CEA in the hope of perhaps shedding new light on the controversial subject of ball lightning⁴, since according to published statistics⁵ ball lightning is mentioned in more than 40% of the cases in which an observer describes a nearby lightning stroke.

The experimental lightning station was installed by EDF⁶ at Saint Privat d'Allier in the Massif Central, a region where the isokeraunic (thunderstorm) level is about 32. The area is rather flat locally, at an altitude of 1,100 m in the vicinity of smooth mountains which reach 1,300 m. The station consists of three main parts: the staff shelter, which contains the control desk and various cameras; the EDF tower; and the CEA range. An observation hut has been installed at a distance of 2.7 km from the main complex.

The EDF metal tower is 24 m high and is 110 m from the shelter. During the 1973 investigation, rockets were launched from a platform situated half way up the tower under a copper ring, 4 m in diameter, fixed to the top. It was expected that the metal wire carried through the ring by the rocket would make an electrical contact sufficient to conduct the lightning current to the top by way of the ring. All lightning, except one, however, struck the platform directly at the first stroke. When the flash comprised several strokes the subsequent ones were captured by the ring. Consequently, for the 1974 investigation the tower was modified for launching the rockets from its top. Four launchers were permanently loaded on the platform in 1973 and six on the top in 1974.

Fig. 1 Triggered lightning photographed from a distance of 2.7 km.

The CEA range was installed to provoke the interaction of lightning strokes and of lightning current with natural materials. The underlying idea is that some organic or powdery material is present in many instances when ball lightning occurs. This has been noticed already by some ball lightning theorists. So in our experiments lightning was also attracted to the ground in a meadow where two launchers were installed in 1973 and four launchers in 1974. First, experiments were performed with the wire reel laid on the ground. Later it was placed on a porcelain insulating pillar about 1 m high. This was tried in an attempt to delay fusion of the wire and to get bigger strokes. Finally, during the 1974 investigation, each reel was fixed to the top of a vertical pipe 1.5 m high and 14 cm in diameter, made of asbestos concrete and internally coated with soot. This tentative disposition was adopted to try to reproduce the creation of ball lightning when a chimney is struck by lightning. Measurement of peak lightning current is performed with magnetic link arrays, nine links being placed on wooden supports with threefold symmetry around each pipe.

The station is equipped with several devices for storm detection and electric field measurement^{7,8}. During storms the decision to fire a rocket depends on the indication of a field mill electrometer. We used standard anti-hail rockets (Ruggieri type 614) attached to a 0.2 mm steel wire unwinding off a reel. The reel is supplied with a cylindrical metal casing fitted with a conical nozzle and brake; it is sufficiently small ($h = 20$ cm, outer diameter = 5 cm) for easy fixing at the place where one wants the lightning to strike. The electrically fired rocket pulls the wire to a height of 700 m in about 5 s. Then it is automatically destroyed in accordance with safety regulations.

Between mid-July and the end of September 1973, 12 triggerings were obtained with 20 technically correct launchings. In 1974, eight triggerings resulted from 10 correct launchings between June 1 and October 15. Eleven flashes out of a total of 20 had at least one intensity peak greater than 2 kA, the highest value being 19 kA.

Triggered lightning seems to be similar to upward natural lightning striking tall structures^{9,10}. As a rule, triggered lightning begins with a slow discharge, the intensity of which remains in the kiloampere range, or less, with a rise time longer than 10 μ s and a total duration of a few tenths of a second. In nine cases the slow discharge was followed by several restrikes with steep-front, high current peaks of short duration.

In the case of negatively charged clouds, pictures taken from the distant observation hut show that branching may be very important (Fig. 1). On this photograph the vertical visible extension is of about 2 km and the total lateral extension at least 4 km. The overexposed part at the bottom corresponds to the 150-m length of vaporised wire. The shape of the branches is characteristic of upward discharges. This is confirmed by cine film (48 frames s^{-1}) which shows a rather low upward speed of about 2×10^4 m s^{-1} at the beginning. Subsequent strokes are correlated with the successive illumination of various branches in which the propagation is too fast for our measurements.

With positively charged clouds, triggering seems more difficult in the sense that the field at the ground has to be higher for the same probability of success. In this case the discharge also propagates upwards but with a greater speed of the order of 10^5 m s^{-1} or more; branches are also less numerous. Of course these conclusions are tentative since they are based on a small number of events.

We have not observed anything comparable with the more remarkable tales of ball lightning folklore. Nevertheless our search for ball lightning has not been fruitless. Several observations have been made which have a connection with the subject and which may help to explain some occurrences of ball lightning.

The beaded appearance of triggered lightning during its decay was noticed when triggering was unexpectedly produced by a plume of water ejected by a submarine explosion¹. In our experiments, the beaded decay has shown up systematically, and increasingly with increasing lightning strength. It has been

registered on pictures taken mostly with a camera (16-mm, 150 frames s^{-1}) at a distance ranging from 70 to 110 m, and with focal lengths from 30 mm to 120 mm.

The beads generally have an initial diameter of the order of 40 cm which decreases gradually with a total lifetime of 0.3 s at most.

During long-lasting strokes, the initially straight channel adopts on a progressively more tortuous shape and the biggest beads occur where tortuosity is a maximum. Since there is a positive correlation between diameter and lifetime, it follows that at the end of the decay there are one or two luminous balls only. In general these objects have an upward motion of 1 or 2 m s^{-1} , which gives an overall picture consistent with the hypothesis of a gradually cooling spheroid of hot gas¹¹.

Moreover, it seems unjustified to invoke a persistent current to explain the long lifetime¹². This results from the following observation: on one occasion, after a stroke lasting 0.66 s on the EDF tower, a luminous spheroid was floating half way up

Fig. 2 A stroke on the tower. Pictures taken with a 16-mm cine camera at 100 frames s^{-1} . *a*, At $t = 0.66$ s after initiation of a stroke reaching the platform the "beads" in the decaying channel are irregular, as is generally the case after powerful strokes of long duration; *b*, at $t = 0.68$ s a restrike occurs, illuminating the smoke trail left by the rocket, and stops on the upper structure of the tower leaving undisturbed the luminous remains below; *c*, at $t = 0.70$ s the process continues.

Fig. 3 Layout of a pair of launchers on the ground range and location of luminous spots.

between the launching platform and the metallic ring, then a subsequent brief stroke fell on the ring without disturbing the slow decay of the luminous object below. It is evident that, in the case of a decay governed by the input of an external current, a modification would have resulted from the change in electric field associated with the second stroke.

It can be stated also that the residue of the vaporised wire has little influence on the appearance and the behaviour of the beads. This is deduced from the following sequence of events:

In most cases the current in the first strike rises very slowly. The wire begins to break at the point where it leaves the reel, where the mechanical stress is a maximum. Then a straight arc is drawn upwards between the immobile reel and the lower end of the ascending wire. Complete vaporisation of the wire occurs only when the arc has reached a length of a few metres (typically 5 m). Then, as long as the current flows, the lower few metres emit much less light than the upper part, which is contaminated by metal vapour, but the difference disappears early during the afterglow. The similarity of the beaded decay in the lower and upper sections is indicative of the lack of influence of condensed wire residue. Incidentally, it proves also that the temperature of the beads must be rather low.

Photographic records reveal that during flashes striking pipes 3 and 4, light emission occurred at the foot of wooden posts supporting a wood fence erected for security reasons around each launcher. The general layout is shown in Fig. 3 which shows two launchers (L₃, L₄), two sooted pipes (P₃, P₄), the fences with the posts around L₃, L₄, the earthing cable (EC) and three places (O₁, O₂, O₃) where light emission has been noticed. For practical reasons the records on O₁ are more numerous and have a better quality than those concerning the two others. Since the few records on O₂ and O₃ bear much similarity with O₁ the following discussion will refer to O₁ only.

Photographic images have been obtained at a distance of 67 m with a 16-mm cine camera (150 frames s⁻¹, $f = 40$ mm) operated by us, a still camera ($f = 80$ mm) and another 16-mm cine camera (66 frames s⁻¹, $f = 10$ mm) operated by F. Rühling (Institut für Hochspannungs und Anlagentechnik, Munich). Light from O₁ has been observed twice: first during a flash on P₄ with a maximum negative current of 2.8 kA and 12 min later during a flash on P₃ with a maximum negative current of 15.3 kA. The flash on P₄ lasted 0.55 s with fluctuations but without a sharp restrike. In that case, the light from O₁ appeared at $t = 0.23$ s after breakdown, grew progressively for 0.06 s, fluctuated in phase with the flash and disappeared at $t = 0.55$ s when the main channel began to break into beads. The flash on P₃ had a total duration of 0.8 s. It began with a discharge lasting 0.42 s and ended with eight restrikes. Light from O₁ appeared at $t = 0.21$ s after breakdown, ceased at $t = 0.44$ s and appeared again with each restrike until $t = 0.8$ s.

The light-emitting region was stationary, in contact with the ground at the place where the post enters the earth. Its shape seems roughly spherical with a diameter of about 25 cm but

because of the poor resolution these observations are somewhat tenuous.

The hypothesis of an accidental reflection of light from the flash is unfounded because in both cases the object appears later than the time of maximum brightness for the main channel. Visual inspection of the spot did not reveal anything special. No marks or burns were visible on the grass or on the post.

The most probable explanation is that it was due to the influence of electric currents circulating in the ground during the flash. These currents start from the earthing cable connecting L₃, P₃, P₄, L₄, which is buried only a few centimetres deep. It is not surprising that some underground outgassing occurs and that the gases escape at the point where the posts puncture the upper layer. It remains to be decided whether the light comes from hot gases only or from a combustion involving hydrogen or methane, for instance, or from a localised electric discharge mechanism. The fact that O₁ was pulsating in synchrony with the restrikes does not support the combustion hypothesis. Further experiments are planned to clarify the question.

We thank colleagues at the CEA and EDF and M. Perroud and the staff of the Laboratoire d'Applications Spéciales de la Physique for help. The local authorities of EDF and M. Bouchet solved many practical problems.

Isoelectric point of the edge surface of kaolinite

THE nature of the particle-particle interactions in clay suspensions is of great technological importance since these interactions determine the flow properties of suspensions used in, for example, ceramic manufacture and paper making, and as oil drilling fluids. They also influence profoundly the structure and behaviour of soils. Clay particles are of a plate-like morphology and thus exhibit two types of surface, the edges and the basal faces. Consequently, a variety of different types of particle-particle interaction are possible in aqueous clay suspensions^{1,2}. For example, structures consisting of individual particles coagulated in an edge-face or an edge-edge arrangement have been proposed as well as face-face (or 'card-pack') aggregates which may themselves be coagulated in edge-face or edge-edge modes³.

The type of structure present in a clay suspension is determined by the electrical double layers at the two interfaces. The results presented below are a preliminary report of a study designed to evaluate the influence of electrical double layers on the properties of aqueous kaolinite suspensions³ and hence to elucidate the conditions in which the

Fig. 1 Bingham yield values of homoionic sodium kaolinite as a function of pH and NaCl concentration. ○, 10^{-4} M NaCl; △, 0.017 M NaCl; ●, 0.034 M NaCl; ▲, 0.12 M NaCl.

different types of particle arrangement exist. They have also enabled a value to be determined for the isoelectric point of the edge surface of kaolinite.

The electrical double layers at edges and faces must differ either in the magnitude or in the sign of the surface potential in order to account for edge-edge and edge-face structures, since a face-face coagulated structure would be the condition of lowest free energy if the electrical double layers on all surfaces were identical and there was no potential energy barrier to coagulation. It is usually considered⁴ that the basal face of a kaolinite crystal is a surface of constant charge density, determined by the amount of isomorphous replacement within the crystal lattice; on the other hand, the edge surface has a surface potential which depends, as in the case of an oxidic surface, on the adsorption of the potential-determining hydrogen and hydroxyl ions². Schofield and Samson⁵ have demonstrated that at low pH values (below the isoelectric point of the edge surface) edge-face structures exist because the positively charged edges are electrostatically attracted to the negatively charged basal faces. At pH values slightly above the isoelectric point of the edge surface, however, the system becomes deflocculated at low ionic strengths, since the edge surface potential is negative and large, and results in high potential energy barriers to all types of coagulation.

The flow curves of clay suspensions frequently approximate to the Bingham model in which a certain yield value must be exceeded before flow is induced. The Bingham yield value is a function of the number and strength of the particle-particle linkages and is therefore a sensitive measure of the degree of coagulation. The addition of indifferent electrolyte reduces the Bingham yield value of edge-face coagulated systems by compressing the two electrical double layers and thereby reducing the electrostatic attraction. Conversely, the addition of electrolyte at high pH values increases the Bingham yield value by compressing all electrical double layers, thus lowering the energy barrier to van der Waals' coagulation. It can be argued that, at the isoelectric point of the edge surface, the system should already be fully coagulated in an edge-edge structure, even at low ionic strengths. Thus, the addition of indifferent electrolyte should have no effect on the yield value until sufficient electrolyte is added to promote face-face aggregation. If this argument is correct, then,

providing the ionic strength is not too high, plots of the Bingham yield value of kaolinite as a function of pH, each at a different ionic strength, should all coincide at one single pH value, the isoelectric point of the edge surface of a kaolinite crystal. This prediction has been validated by our study.

The rheological properties of suspensions containing 9 wt% of a highly crystalline kaolinite sample from a Cornish deposit, previously purified and converted to the homoionic sodium form according to the method of Schofield and Samson⁵, were investigated as a function of pH at different concentrations of NaCl (ref. 3). Flow curves were determined using a concentric-cylinder viscometer and in each case the data, determined at relatively high rates of shear, were extrapolated to give the Bingham yield value. Figure 1 shows the results, which are as predicted. The point of coincidence is at a pH value of 7.3 and we suggest that this is the isoelectric point of the edge surface of a kaolinite sample prepared by this method. It is clear that at pH values below this isoelectric point the yield value increases due to the onset of edge-face coagulation, whereas above it the system becomes progressively deflocculated. At pH values both above and below the isoelectric point of the edge surface, the effect of indifferent electrolyte is to change the yield value towards the value shown at the isoelectric point, that is, to promote edge-edge coagulation. This has been further corroborated³ by the fact that progressively higher electrolyte concentrations are required to achieve this yield value as the potential of the edge surface increases both above and below the isoelectric point.

The value of the isoelectric point obtained is comparable with the values obtained by others^{5,6}, and with the pH value of zero adsorption of hydrogen ions found by Flegmann *et al.*⁷. Flegmann *et al.*, however, suggested the isoelectric point of the edge surface of kaolinite to be at a pH value of 6, the maximum in the yield value-pH plot. This maximum was attributed to an edge-edge structure, but it can be seen from this work that this is a misinterpretation of the rheological data. Quirk⁸, however, has detected positive adsorption of chloride ions at pH values as high as 9-11 but it is not certain that a small amount of iron oxide impurity in his clay did not affect these results to some extent. Other values reported in the literature do not necessarily refer to clays prepared in the same way as reported here. As part of this study, certain commercial and natural clays have been investigated and the results compared with the model system described here. Different apparent isoelectric points were obtained which depended on the previous history of the clay samples. These results will be published elsewhere, along with a more detailed account of the influence of the electrical double layers on the rheological and sedimentation behaviour of the kaolinite sample reported here.

These results suggest that edge-face structures exist only below the isoelectric point of the kaolinite edge surface at low ionic strengths. Edge-edge structures exist to varying extents at all pH values at moderate concentrations (≈ 0.1 M in a 1:1 electrolyte), and at pH values around and slightly above the isoelectric point of the edge surface at low electrolyte concentrations. At higher electrolyte concentrations (> 0.1 M) it is suggested³ that face-face aggregates are formed at all pH values.

Mechanism for shear delamination under dynamic loading

WE describe here a debonding mechanism for interfaces between dissimilar materials in conditions of dynamic loading, and we deal, in particular, with coated substrates that are impacted by solid or liquid projectiles. Protective coatings are commonly used to enhance the resistance of materials to impact erosion; for example, non-metallic fibre-reinforced composite materials are found to be very susceptible to impact erosion unless a suitable thin coating is applied. For these composites, certain elastomers can be successful as coating materials, even though they do not, intrinsically, possess high strength. Coatings of this type reduce the pressures that are transmitted to the substrate by presenting a lower dynamic impedance to the impacting body. The interfacial adhesion between the coating and substrate is of great importance because it enables the substrate to reinforce the coating by restricting the lateral strain, and therefore the stress, within the coating. When adhesion is lost, the coating itself becomes quickly eroded. Thus, the bond between the coating and substrate is often of great significance to the success of a coating-substrate system.

The impact of liquid drops on to a coated substrate has been considered by a number of authors^{1–3}, but little attention has been paid to the precise mechanisms of the adhesion breakdown between the coating and substrate. High speed photographic observations of the process of delamination under liquid impact^{4,5} and examination of

Fig. 1 Experimental arrangement for the high speed photography.

Fig. 2 The front of a water jet (750 m s^{-1}) impacting a PMMA layer that is bonded to a glass block. The jet head diameter is $\approx 3 \text{ mm}$. Frames are selected from an Imacon sequence of $10^6 \text{ frames s}^{-1}$. P, Compressive stress front in the PMMA; G, transmitted stress in the glass block.

impacted laminates have shown that the delaminations are usually composed of distinct coaxial annular regions. This suggests that several mechanisms are operative. Often the interface on the impact axis has not failed, and the total delamination is an annulus. This behaviour cannot be explained by the commonly cited mechanism of tensile failure resulting from reflected or dispersed stress waves, because such interactions lead to maximum tensions developing on the impact axis. Therefore the creation of shear stress along the interface must be considered. When stress waves from an impact meet an interface, shear stresses can be set up by several mechanisms; for example, they can arise from the incident pulse of shear stress (which is usually of a low magnitude) or from the oblique incidence of the main compressive pulse⁶. The high speed photographic sequences presented here illustrate another form of shear debonding of comparable magnitude to the latter. The mechanism arises from the wavefront separation that occurs when stress propagates parallel to an interface between two media which have different stress-wave velocities.

A schematic diagram of the experiment is shown in Fig. 1. The front of a water cylinder impacts a polymethylmethacrylate (PMMA) layer 3 mm thick, that is bonded to a glass block. The jet velocity in the experiments was 750 m s^{-1} (see also refs 7 and 8). A sensitive shadowgraph optical system⁴ was used to make the stress waves generated by the impact visible. The high speed photographs were taken with a Hadland Imacon framing image converter camera operating at $10^6 \text{ frames s}^{-1}$, and selected frames from two sequences are shown in Figs 2 and 3.

When the front of the jet first strikes the PMMA surface, the liquid behaves compressibly for about $1 \mu\text{s}$ and a very intense pressure, $\sim 1 \text{ GPa}$ is developed⁷. When the pressure front in the PMMA, P, reaches the PMMA-glass interface, it generates the transmitted pulse G in the glass. The stress propagation velocity in the glass is high ($5,600 \text{ m s}^{-1}$) compared with that in the PMMA ($2,700 \text{ m s}^{-1}$ to $\sim 3,200 \text{ m s}^{-1}$, depending on the stress level). Therefore, there is a critical

angle of incidence of the diverging pulse P beyond which no stress is transmitted across the interface. A non-delaminated region corresponding to the size predicted by this angle is found during high speed photographic observation of coated substrates⁵. Outside this diameter in the region of the interface, front G in the glass overtakes pulse P travelling in the PMMA: these separated fronts are seen clearly in frame 3 of Fig. 2. In frame 2 of Fig. 3 disturbance H, a 'headwave' in the PMMA, is generated by the faster stress front, G, in the glass. It indicates that a high stress is being transmitted across the interface by the separation of the wave fronts, that is, that shear strain is developed between stressed glass and unstressed PMMA. This is a potential delamination mechanism.

The theory of stress waves in these conditions has been developed by many authors (see, for example, refs 9 and 10). The conditions for delamination and its effect on the subsequent wave propagation are not, however, discussed. High speed photographic studies of spherical stress waves^{11,12} have shown that both the normal and tangential stresses at the interface achieve large values at various stages in the propagation history. The analogous situation of plane wavefronts propagating parallel to the boundary between coupled bars of dissimilar media has also been considered by a number of authors (see, for example, refs 13 and 14). They have shown that the coupling force can be of sufficient magnitude to cause debonding.

Observations of the formation of delamination fractures have shown that it is a very complex process, and involves many different mechanisms. Velocities of delamination growth exceed the maximum tensile crack velocities, and vary according to the stress wave propagation conditions. The simple mechanism illustrated here may not be the only one operating, but it does involve stress levels that are significant for many bonded interfaces. Even if it does not cause complete failure of the bond, it may cause nucleation of local failure sites which are then extended by the succeeding stress history.

Fig. 3 As Fig. 2, but different illumination conditions also show the headwave, H. 1 μ s between frames.

An important point to note is that this mechanism will operate between media which are 'acoustically matched' (that is, media which have the same value for the product ρC , where ρ is the density and C is the stress wave velocity). Acoustic matching has often been considered as a means to minimise interfacial stress by eliminating reflected wave components. The shear mechanism of wavefront separation, which relies on a mismatch of C and not ρC , will, however, still in general operate. We have observed annular delaminations between such acoustically matched layers, which can be explained by this process. We conclude that, although acoustic matching of coatings may be beneficial, it is also important to choose materials which have similar values of C . In practice, this may be difficult to achieve by using a single coating material, but multiple coatings, with

a gradation of physical properties, could overcome this problem.

Large scale changes in North Sea phytoplankton

CONTINUOUS plankton recorders (CPRs) are towed^{1,2} at approximately monthly intervals in the North Sea along standardised routes at a standard depth of 10 m. Analysis of long term results has revealed large scale trends and changes³. Here I deal with changes in the phytoplankton from 1948 to 1973 as evidenced by results from area C2 (Fig. 1) in the western North Sea.

As the CPR is towed through the water it filters the plankton on to a continuously moving band of silk with apertures of approximately 270 μ m. Phytoplankton is analysed in these samples in two ways. First, 'phytoplankton colour' is visually assessed into three categories⁴ to give a relative estimate of

Fig. 1 North Sea standard areas.

Table 1 Species included in diatom and *Ceratium* spp. totals

Diatoms	<i>Ceratium</i>

* <i>Nitzschia delicatissima</i> Cleve	

*All species typically form chains which increases their chance of being entrapped in the CPR silk.

†The large species *T. longissima* occurs free but frequently forms dense matted colonies.

All *Ceratium* species are large and likely to be well sampled by the CPR.

phytoplankton standing crop (visual chlorophyll). Second, since 1958, species have been identified and counted⁵. Most phytoplankton passes through the coarse meshes of the CPR but comparisons with water samples⁶ and the results of the survey indicate that the portion retained seems to reflect changes in the abundance and distribution of the major components of the phytoplankton. The large number of CPR samples taken over extensive areas smooths the effect of patchiness and gives gross

estimates of abundance which are comparable within the CPR survey.

The monthly means for both methods of analysis are calculated for samples in 2° longitude × 1° latitude rectangles and then averaged into larger 'standard areas'. Results for Standard Area C2 are presented as contoured month/year diagrams in Figs 2–4. The pattern of phytoplankton change observed in Standard Area C2 is, in many respects, typical of the whole of the North Sea. *Ceratium* spp. and diatoms represent the totals of the average abundance of the seven most common *Ceratium* species and 16 diatoms in the North Sea (Table 1).

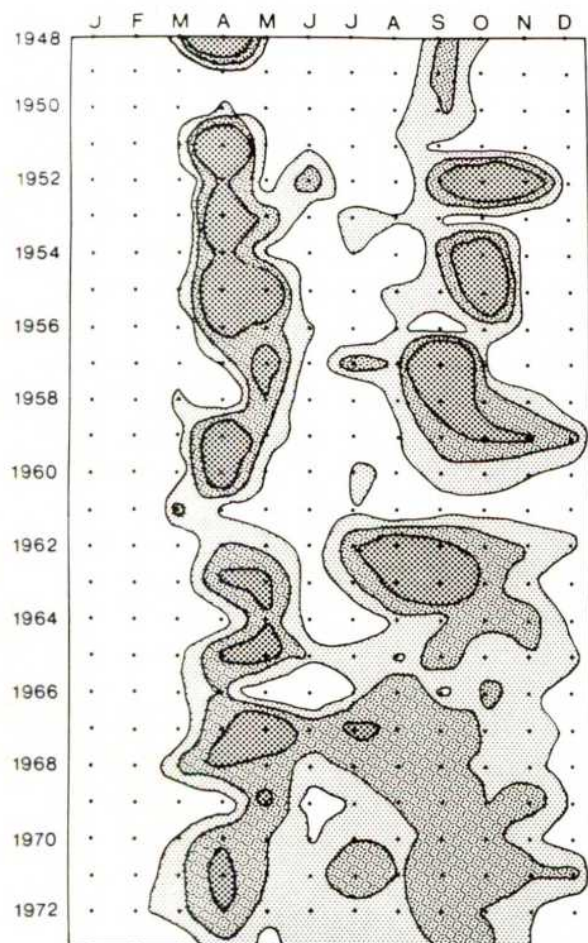

Before 1965, the analyses of phytoplankton colour revealed distinct spring and autumn blooms (Fig. 2) but after that date the distinction between the two blooms became less marked and the productive season became longer, although the autumn bloom declined in intensity. *Ceratium* spp. (Fig. 3) have shown little change in either timing or abundance since 1958.

The diatom count decreased markedly after 1965 (Fig. 4). The autumn bloom declined drastically and winter and summer diatoms almost disappeared. A more gradual but still considerable decline occurred in the spring bloom.

To some extent, there seems to be an inverse relationship between the pattern of phytoplankton colour and diatom changes. The diatoms have declined in abundance (especially in the summer, autumn and winter months) as phytoplankton colour has increased. Therefore, it seems that phytoplankton other than diatoms and *Ceratium* spp. as measured by the CPR has caused the general increase in colour. Other groups such as the silicoflagellates and coccolithophores only occurred in small numbers and *Phaeocystis* showed a decline similar to that of the diatoms after 1965. One possible explanation is that there may have been an increase in the abundance of microflagellates which partially disintegrate in formalin leaving their chloroplasts to add to the coloration of the silks. Such microflagellates would not be identifiable in CPR samples but could have caused the increase in phytoplankton colour. A similar replacement of a diatom by a flagellate population was described by Grøntved⁷ as part of the seasonal succession of the phytoplankton of the North Sea during 1947.

The pronounced change in the phytoplankton of area C2 which took place around 1965 is coincident with the return of plankton, which was typical of the 1920s, to the English Channel off Plymouth⁸. This reversal in Channel plankton was attributed by Russell *et al.*⁸ to climatic change which may have led to an increased Atlantic inflow into the North Sea. Unfortunately, the CPR survey did not commence in the North Sea until 1931 so that it is not possible to determine whether the recent

Fig. 2 Phytoplankton colour (visual chlorophyll) in Standard Area C2.

Fig. 3 Abundance of *Ceratium* in Standard Area C2.

changes in the North Sea are a return to the conditions of the 1920s.

If climatic changes are causing the considerable changes in the plankton of the North Sea and the English Channel, then they seem to be influencing the zooplankton and phytoplankton of the two areas in different ways; both zooplankton biomass and diatoms are increasing in the English Channel off Plymouth⁸, whereas in the North Sea they are declining⁹. But productivity as measured by ¹⁴C has increased in the English Channel since 1965 (ref. 8). While there are no comparable time series of productivity measurements in the North Sea, the standing crop as determined from crude estimates of phytoplankton colour certainly seems to have increased.

A second possible alternative cause of the phytoplankton changes is eutrophication caused by increasing nutrient levels⁹ in the North Sea. This seems unlikely, however, because eutrophication arising from pollution, only seems to be a potential problem in coastal waters¹⁰ and not in the offshore waters of area C2.

The changing composition of the phytoplankton in area C2 since 1965 is likely to be reflected at higher trophic levels. During the same period there has been a parallel decline in the

zooplankton biomass of the North Sea³. It is possible, therefore, that the plants which seem to be replacing the diatoms since 1965 may be less readily utilised as food. Contemporary changes have also taken place in the fish larvae of the CPR survey (S. H. Coombs, personal communication). We are now attempting to identify the organisms which seem to be replacing the diatoms and to determine whether the changes in the North Sea are cyclical and related to climatic change or to other as yet unknown influences.

This work forms part of the programme of the Institute for Marine Environmental Research, a component of the Natural Environment Research Council. I thank Dr J. M. Colebrook and Mr H. G. Hunt for assistance with computing and Miss S. Bradley for data processing.

Is the illusory triangle physical or imaginary?

MOST pictures of visual interest contain a large amount of detailed information. Studies have shown that a great deal of these data can be filtered out without destroying a subject's or a machine's ability to recognise even quite complex objects¹⁻⁴. The resulting benefits are economy of memory store and considerable flexibility in the shape and detail of objects classified as the same.

Such filtering must to some extent distort our own visual perception and can account for certain geometric and contrast illusions⁴. There has been recent interest in illusory contours⁵. Figure 1a shows an example of an illusory contour perceived in a Kanizsa triangle. A black triangle is perceived as a unitary form separated in depth over a white triangle. The question now arises, what would happen if we filter this figure to get rid of the redundant information? In other words, what form remains if the detailed information (the higher spatial frequencies) not necessary for the identification of the original pattern features are removed?

This filtering was carried out as follows. The two-dimensional discrete Fourier transform of the original picture was made (Fig. 1b). (A log transform was used on both the transform and filtered pictures to compress the intensity levels and provide the maximum detail.) The magnitudes of these spatial frequencies were decreased according to the attenuation characteristics of the visual system⁶ (Fig. 1c). An inverse Fourier transform reconstructs this attenuated spatial frequency data (Fig. 1d). The filtered picture results in smoothed pattern features and a loss in contrast in the lines, but enough resolution is still retained to provide an illusory triangle. There is still no clue from this picture, however, as to how the original pattern features interact to provide the illusory triangle.

Further spatial filtering was carried out to remove even more redundant pattern information. Previous experiments on filtering suggest that the low spatial frequencies will provide sufficient information for classifying forms¹⁻⁴. When this filtering was accomplished by removing three-fourths of the higher spatial frequencies (Fig. 1e), we note a generally homogeneous dark triangle surrounded by a somewhat homogeneous lighter

Fig. 4 Abundance of diatoms in Standard Area C2.

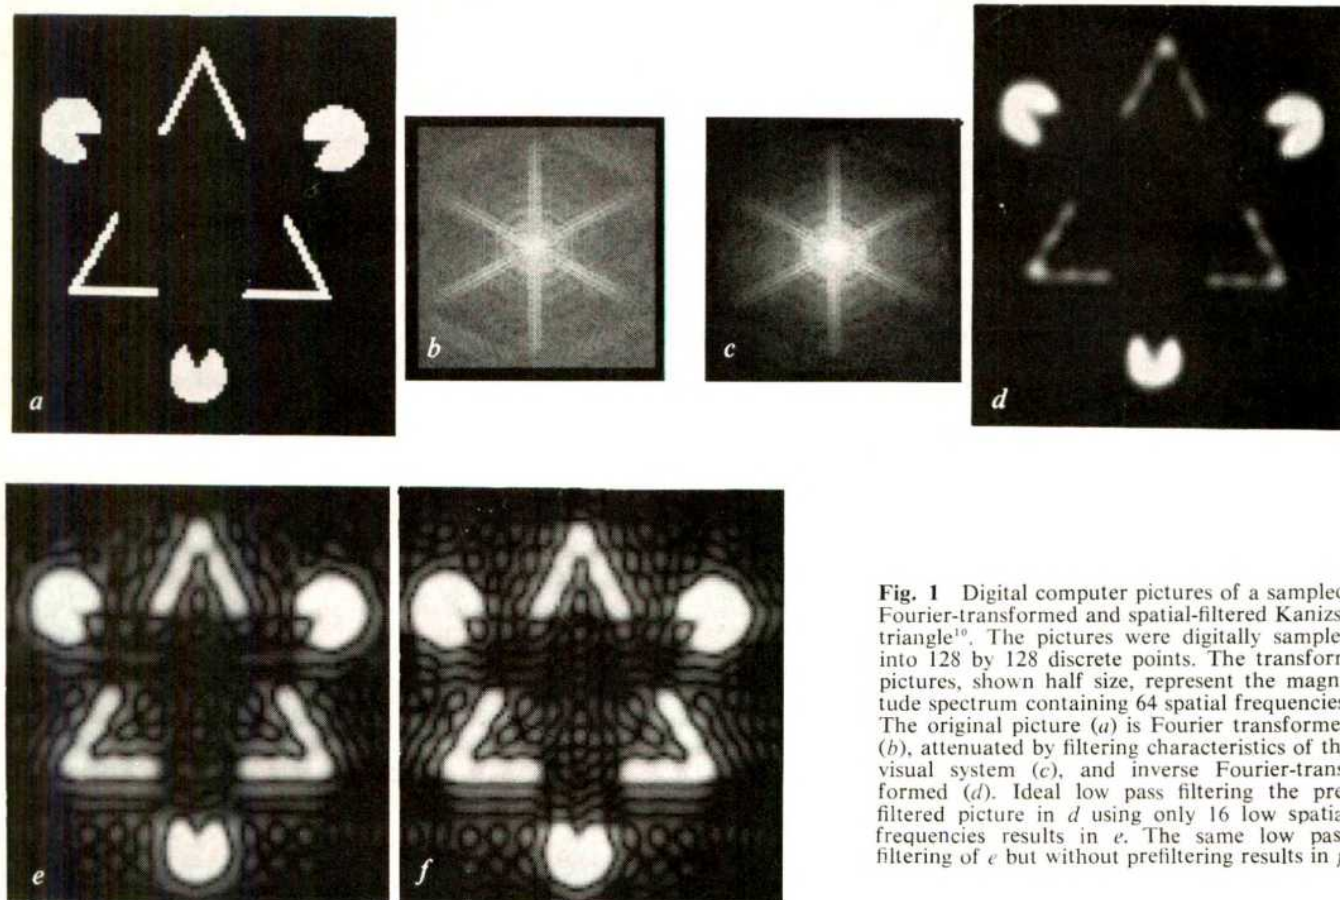

Fig. 1 Digital computer pictures of a sampled, Fourier-transformed and spatial-filtered Kanizsa triangle¹⁰. The pictures were digitally sampled into 128 by 128 discrete points. The transform pictures, shown half size, represent the magnitude spectrum containing 64 spatial frequencies. The original picture (a) is Fourier transformed (b), attenuated by filtering characteristics of the visual system (c), and inverse Fourier-transformed (d). Ideal low pass filtering the pre-filtered picture in d using only 16 low spatial frequencies results in e. The same low pass filtering of e but without prefiltering results in f.

triangle and area. Note in particular the top dark horizontal boundary line of the dark triangle. (This sharp boundary results from the most linear sectorised disk and smooth line features of the original pattern. Other similar pattern features of the original triangle are jagged because of the coarse quantification process, and result in less well defined regions in the filtered pictures. Further improvements in techniques will provide even more striking results.) It seems that as in previous results, limited regions of low spatial frequencies do provide pattern information that is not readily apparent from analysing the original pattern features.

Have the initial filtering characteristics of the visual system attenuated the low spatial frequency information in such a manner as to aid the detection of the 'illusory' triangle? We answer this question by low pass filtering the original picture directly. The resulting picture (Fig. 1f) shows a somewhat less homogeneous dark triangle region. This result suggests that the low spatial frequency attenuation characteristics of the visual system do aid the formation of the 'illusory' triangle.

To convince a blind mathematician that a triangle really exists, one could have simply correlated the original pattern with an actual triangle. Correlation would provide an independent and objective measure of the degree to which the illusory triangle exists in the original pattern. Previous pattern classification studies, however, have shown that the low spatial frequencies provide generalised form information that is relatively insensitive to discriminable differences between objects classified as the same. Therefore, to be consistent with previous analysis and not treat this pattern in any way different from others, we compared just the low spatial frequencies of the original pattern with the low spatial frequencies of a black triangle of similar size and orientation. They correlate.

It should be stressed, however, that not all subjective contour patterns may be explained so easily by such filtering or correlation techniques. If the sectorised disks are replaced with small dots, as Gregory has done, an illusory triangle does exist although it is markedly less evident⁵. Initial filtering analysis of a similar pattern has yielded promising but not too convincing

results, because of the relatively small energy contained in the dots. Again, further research will be needed to improve techniques and determine whether or not additional mechanisms are being used to detect and process other illusory contours.

In summary, the Kanizsa triangle has been filtered in the above well defined manner. The final picture contains a black triangle, but mathematically we have not informed the system used about a triangle. We have not explicitly manipulated the original pattern features, nor have we provided additional cognitive clues. Neither the Fourier transform nor the filtering acting on the original pattern have generated the illusory contour triangle. Rather, the filtering has isolated and enhanced the illusory triangle information that was implicit in the overall spatial relationships of the original pattern features. Therefore the original picture must have contained the triangle. It is therefore not surprising that our visual system detects it. This analysis is consistent with visual spatial information being filtered by quasi-independent spatial frequency-orientation channels as evidenced by neurophysiological and psychophysical studies⁷⁻⁹.

Intrauterine nutrition and aggression

WITH the increase in conflict and aggression in human society, the underlying causes of aggression take on added significance. The laboratory investigation of human aggression is difficult primarily because of ethical considerations. Animal aggression must therefore serve as a model for the experimental study of suspected causes of aggression. One potential cause is malnutrition, which has been assessed by studies of the effects of prenatal zinc deficiency and intrauterine undernutrition on aggressive behaviour in the adult rat. Prenatal zinc deficiency was chosen because it has been found to significantly reduce the size of the brains of foetal¹ and neonatal rats², to impair the synthesis of DNA in the rat brain³, and to decrease the activity of RNA polymerase in neonatal rat liver⁴ and brain⁵. When zinc deficiency is very severe an increased incidence of central nervous system teratology occurs in the foetal rat⁶. Behavioural deficits such as impaired avoidance learning have also been observed^{1,7}.

Fig. 1 Comparison of food consumption among three groups of dams. AL dams (.....) ate significantly more food ($P < 0.001$) than the ZD dams (—) during the zinc-deficient period. PF dams (---) were given the same quantity of food as eaten by the ZD dams during this period. There were no differences among the three groups during the normal diet periods. Day 0 is the day of delivery. a, Normal diet; b, zinc-deficient diet; c, normal diet.

This report shows that adult female rats whose dams suffered prenatal zinc deficiency (ZD) or undernutrition as a result of pair feeding (PF) are significantly more aggressive at a high level of shock (1.6 mA) than adult female rats whose dams were fed *ad libitum* (AL) throughout pregnancy; and that the ZD female rats are more aggressive than the PF female rats. At a lower level of shock (1.3 mA), PF and AL female rats display a similar level of aggression well below that of the ZD female rats.

Thirty pregnant Long-Evans rats were randomly divided into three groups. The dams were housed in plastic cages in a room that was controlled for temperature and humidity. Starting on day 14 of pregnancy, 10 dams (ZD) were fed a biotin-enriched sprayed egg-white diet which contained less than $1 \mu\text{g}$ zinc per g (ref. 2) and deionised water. As zinc deficiency causes anorexia, a second group of 10 dams was individually paired (PF) with the ZD dams and fed the same quantity of the diet as was consumed by their ZD partners (Fig. 1). The PF dams were supplemented with $50 \mu\text{g}$ zinc per ml of drinking water. A third group of 10 dams (AL) were fed the same diet *ad libitum* and given the zinc-supplemented water. On day 20 of pregnancy, all dams were taken off the zinc-deficient diet and fed Purina labora-

tory chow⁸ *ad libitum* and tap water. After delivery, all the dams and their pups were continued on the chow *ad libitum* and tapwater. The reduced food consumption during the zinc-deficient period had a marked effect on the mean weights of the ZD and PF dams (Fig. 2). For the first 40 d of life, the ZD pups were smaller than the PF and AL pups, but by day 75, there were no differences among the three groups (Table 1).

When the pups were 75 d old, 10 females from each group were randomly selected and tested for aggression. The 10 females in each group were divided into five pairs for a total of 15 pairs. Each pair was tested for aggressive behaviour in a clear Plexiglas chamber ($32.0 \times 25.5 \times 30.5$ cm). The grid floor consisted of 0.3-cm stainless steel rods spaced 1.9 cm from centre to centre. The rods were electrified by a Grason-Stadler Model 700 shock generator. The chamber was housed in a box 80 cm high, 61 cm deep and 80 cm wide. Two fans provided intake and exhaust ventilation. Each pair of rats was given 25 shocks per d for 10 d. A modified counter balance procedure (ABBA) was used. On the first 2 d of shock, the intensity was 1.6 mA followed

Fig. 2 Mean weight of dams during the prenatal and postnatal period as a function of dietary manipulations during days 14–20 of pregnancy. See Fig. 1 for coding.

Fig. 3 Comparison of the level of aggression among the three groups of rats at two different levels of shock. ZD rats were significantly more aggressive than either PF or AL rats at both levels of shock. PF rats were significantly more aggressive than the AL rats at 1.6 (b) but not at 1.3 mA of shock (a).

by 5 d of shock at 1.3 mA. The shock was 1.6 mA for the final 3 d. All rats were given 1 d rest after each day of shock. All shocks were 0.5 s in duration and spaced 5.0 s apart. The sessions were videotaped and later evaluated independently by three judges who counted aggressive attacks per pair per session. Aggressive attacks were defined as 'directed movement toward the opponent' which resulted in contact, including at least one of the following responses: biting, sparring, upright attack posturing, or supine submissive posturing adopted by the attacked rat⁸. All judgments were made independently and without knowledge of the group origin of each pair. The reliability between the judges, computed by analysis of variance estimate of reliability⁹, for each day, ranged from 0.95 to 0.99 for the 10 d.

Figure 3 shows the percentage of aggressive attacks displayed by the three groups for the two levels of shock. The total percentage for each group represents the percentage of shocks resulting in aggressive attacks observed in each of the five pairs over 125 trials or 625 trials for the group. Differences between these proportions were compared for statistical significance using a grand combined proportion of aggressive attacks in the error term¹⁰. The level of significance between groups is shown in brackets below the group columns. Only those probabilities $P \leq 0.10$ are shown.

The results show that the AL rats were significantly less aggressive than the ZD rats regardless of the level of shock. Furthermore the levels of aggression remained unchanged for both groups even though the level of shock changed. The offspring of the PF rats who had suffered intrauterine undernutrition¹, were highly aggressive at a high level of shock but were no more aggressive than the AL rats at a lower level of shock. These results suggest that animals that experience prenatal undernutrition during the critical period for brain growth will be more aggressive than normal animals. The results also suggest that animals that experience zinc deficiency during the same period of intrauterine

development are more severely impaired and are even more aggressive than prenatally undernourished rats. Although extrapolation to human aggression is premature, these results do suggest the need for additional research in the field of malnutrition and aggression.

Induction of plants from pollen grains of *Petunia* cultured *in vitro*

THE ease with which plantlets can be produced from somatic tissue, protoplasts and anther cultures of *Petunia*¹⁻³ has prompted us to use isolated pollen grain culture⁴ to determine precisely the stage at which pollen elicits the best androgenic response, with a view to increasing the yield of haploid plants thus produced.

Flower buds in various stages of development from two strains of *Petunia hybrida* L. (Cascade and Rose du Ciel) grown in the greenhouse (the phytotron at Gif-sur-Yvette) were sterilised in a filtered suspension of calcium hypochlorite (7%)

Table 1 Mean weights (g) of pups at 0, 20, 40 and 75 d of age

	0	20	40	75
ZD	5.48	29.8	107.8	224.6
PF	6.09	36.3	129.6	220.6
AL	6.11	37.5	131.2	219.3

for 5 min and rinsed three times with sterile distilled water. Fifteen to twenty anthers were homogenised in a Potter-Elvehjem homogeniser tube with 10 ml of culture medium. The suspension thus obtained was filtered through two superposed sieves of 53 and 73 mesh. New medium was added to give the final concentration desired. This inoculum contained microspores and/or pollen grains according to the age of the anthers used. A large amount of pollen could thus be obtained. The inoculum was rinsed three times with new medium after centrifugation at 120g for 5 min and resuspended in the fresh medium. The pollen grains were cultivated in plastic Petri dishes (6 cm diameter) containing 3 ml of solution inoculated with 10^4 pollen grains per ml. The dishes were maintained at 25 °C for 7 d in the dark and then illuminated continuously with 1,000 lx at a temperature of 28 ± 1 °C. The culture medium consisted of macroelements according to Murashige and Skoog (we used half the concentration described in ref. 5), the microelements and vitamins of Nitsch and Nitsch⁶ supplemented with auxin, cytokinin, boric acid (25 mg l⁻¹), sucrose (2%) and glucose (2%). The pH was adjusted in all cases to 5.6 before autoclaving.

Greenish calluses appeared gradually from the pollen 10–20 d after inoculation into the medium containing various combinations of benzyladenine (BA) and naphthalene acetic acid (NAA). As Table 1 shows, that calluses formed in the combination of BA (0.1 mg l⁻¹) and NAA (0.1 mg l⁻¹) were much more numerous than in other combinations tested. After 30 d of culture 50 pieces of pollen-callus from *P. hybrida* Rose du Ciel were transferred to the same medium; 30 of them gave rise to shoots, 12 produced compact green calluses and 8 did not differentiate.

Fig. 1 *a*, A pollen plant of *P. hybrida* L. Rose du Ciel ($n = 7$), ($\times 1$). *b*, pollen stages: *b*, binucleate; *m*, at first haploid mitosis; *u*, uninucleate ($\times 800$); *c*, and *d*, dividing pollen grains (arrows); *e*, 1 week of culture, $\times 300$; *d*, 2 weeks of culture, $\times 220$; *e*, pollen calluses after 30 d ($\times 1.5$); *f*, shoots from pollen callus after 45 d ($\times 1.5$).

Table 1 Effect of different concentrations of NAA and benzyladenine on formation of pollen calluses in *P. hybrida* L.

Composition of the medium:		No. of calluses formed from isolated pollen grains	
NAA (mg l ⁻¹)	Benzyladenine (mg l ⁻¹)	Rose du Ciel	Cascade
0.1	0.1	2	0
0.5	0.5	13	8
0.1	1	61	58
1	0.1	32	36
1	1	25	30

Pollen extracted from 300 anthers at first pollen mitosis was inoculated for each treatment. Results were scored after 1 month of incubation.

Roots were initiated when the shoots were transferred into basal medium with indolyl-3-acetic acid (0.1 mg l⁻¹) or NAA or without growth hormones. Once they have formed an adequate root system the plantlets (Fig. 1) can be transplanted to pots and raised to mature plants. The same result was obtained when *P. hybrida* Cascade was tested for organogenesis.

The pollen stage at the time of inoculation is an important factor, determining the success or failure of pollen culture. According to our results the microspore inoculated at an early, mid or late uninucleate stage did not divide in any medium or combination tested. Pollen inoculated at, just before or just after the first mitosis (Fig. 1*b*), however, responded to the various media tested with essentially the same results for the two varieties (Table 1).

The course of callus formation in androgenic pollen of *P. hybrida* Rose du Ciel cultured *in vitro* was also followed. Some pollen grains (5–10%) enlarged considerably during the first week of culture (Fig. 1*c*) to form round multicellular masses (Fig. 1*d*), whereas others (90–95%) degenerated progressively. During the third week of culture the round multicellular masses produced irregular calluses (Fig. 1*e*). The formation of many shoot apices could be observed on the same callus within 40 d but only some of them formed shoots after prolonged incubation in the culture medium or after transfer to fresh medium (Fig. 1*f*). As these data show, only a small percentage of pollen grains *P. hybrida* developed into plants—approximately one plant developed from the pollen of eight anthers (that is 20% androgenic anthers). This, however, was a greater percentage of plant morphogenesis than Raquin and Pilet achieved with anther culture (1% androgenic anthers)⁸.

Cytological examination of the root-tip squashes of regenerated plants revealed haploid, diploid ($2n = 14$) and triploid plants among the population. The frequency of haploid plantlet formation was generally low compared with diploid or triploid; of 30 plants initiated from pollen culture, three were haploid, seven diploid and 20 triploid in *P. hybrida* Rose du Ciel. The existence of ploidy differences among the adult population is common in plantlets derived from microspores and can be accounted for by endomitosis or nuclear fusion: in such cases they will be homozygous^{7–10}. Thus, homozygous diploids obtained by pollen culture could eliminate long delays in the production of inbred lines.

Nerves and angiogenesis in amphibian limb regeneration

In the past 150 yr, since the requirement of nerves for amphibian limb regeneration was demonstrated, there has been considerable progress in specifying the nature of the phenomenon but virtually none in understanding the site or nature of the neuronal effect¹. If denervation is carried out early, amputated limbs will not regenerate and may even undergo regression; at later stages in regeneration, when a blastema has formed, regeneration is not prevented by denervation, although in the newt at least, growth in volume is inhibited while growth in length and morphogenesis continue^{2,3}. Studies on the neuronal dependence have shown that any nerve can provide the trophic influence, that neither central nor reflex circuitry is required, and that a threshold number of nerves at the amputation surface is needed⁴. The neurotrophic agents do not determine the nature of the regenerate but only its growth properties⁴, and this is borne out by many biochemical studies, all of which suggest that nerves nonspecifically affect macromolecular synthesis and cell division^{5,6}.

Folkman's work on tumour angiogenesis⁷ has emphasised the importance of vascularisation and blood supply in growth processes, and how little we know of the mechanisms involved in angiogenesis in normal development. He has shown that tumours will not grow larger than about 1-2 mm unless vascularised. This suggested to us a new interpretation for the effect of nerves on limb regeneration. Our hypothesis is that the trophic action of the nerves is not on the growth of the regenerate itself but that the nerves are necessary for the vascularisation of the blastema. Thus, early denervation will prevent regeneration by blocking vascularisation.

The vasculature of regenerating limbs of the newt (*Triturus*

Fig. 1 Vascular changes during limb regeneration in the newt *T. cristatus*. *a*, 7 d after amputation. *b*, pre-small cone phase (10 d after amputation): the avascular rim is now about 0.5 mm wide. The whole mounts are difficult to photograph satisfactorily, low lighting being needed to see the otherwise transparent tissues. When viewed end-on, the avascular tip is very clear. *c*, Small cone blastema: this is now beginning to show signs of vascular buds growing into the proximal parts of the blastema. The stump boundary is shown by the arrows. *d*, Flat-cone blastema: the blastema is now fully vascularised and some thicker vessels are beginning to appear. ($\times \sim 9$).

Fig. 2 Vascular pattern of regenerating and of denervated limbs of the axolotl *A. mexicanum*. *a*, 7 d after amputation: this shows clearly the retracted dermal vasculature, leaving a little more than 1 mm of avascular tissue more distally. The fine anastomosing capillary network can be seen easily. *b*, The innervated (control) limb after 17 d of regeneration. *c*, The limb denervated 3 d after amputation and left for 2 weeks to grow (17 d in total). The control side has formed a highly vascularised large blastema (more than 1.5 mm), whereas the denervated side has formed a small avascular blastema (0.5 mm). (The denervated side shows a small haematoma underneath the blastema. This was more common in denervated animals. Whether this is due to fragility of the vasculature or a loss of the ability of vasoconstriction of the ends of the vessels because of denervation is not known.) ($\times \sim 12$).

cristatus) and axolotl (*Ambystoma mexicanum*) was investigated by injecting Indian ink through a fine glass pipette into the hearts of MS222-anaesthetised animals. The limbs were then amputated, fixed in Bouin's, dehydrated and cleared in methyl salicylate. This technique is crude and cannot be expected to reveal subtle changes in the blood supply, but gross changes have been observed. The vasculature of the whole arm can be divided roughly into two main components. The first appears to be situated in the dermis in close proximity to the surface, forming a sheath over the whole arm. It is made up of a very fine anastomosing meshwork of vessels (10-30 μ m diameter), and gives the appearance, in an Indian-ink injected animal, of lace gloves (see Fig. 2a). These vessels can be shown histologically to surround the numerous dermal glands. The second component comprises all the deeper-lying large vessels that supply the other tissues of the arm. These tend to be coarser in appearance except for the fine vessels in the muscles. These are, however, easily distinguishable due to their parallel arrangement. After amputation, the skin contracts away from the cut surface, taking with it the underlying dermal vasculature (Fig. 2a). Thus, in the first few days of regeneration there is a region immediately below the wound epithelium that is avascular. The wound epithelium thickens to form an apical cap and blastema formation starts⁸. The pre-small cone phase is avascular, but by the small cone stage, small capillary buds are beginning to sprout and invade the proximal blastema (Fig. 1). These are fine vessels and can be traced to the dermal network of capillaries as well as the deeper vessels. The distal part of the small cone blastema still appears to be avascular and these tiny vessels do not get to the distal margin until the large cone stage. The avascular early blastema is more striking in the axolotl than in the newt (Fig. 2a). After the large cone stage, bigger vessels are quite often seen in the blastema. The distal margin of the large cone blastema has a continuous capillary supply underneath it. After the large cone stage, this vascular margin becomes fragmented as the delineation of the digits is made, the avascular spaces corresponding to the tips of the future digits. Tubes of vessels form as the indentations mark off externally the four digits. This description is essentially the same as that of Peardon and Singer⁹ for the newt *Triturus viridescens*.

Vascularisation was also investigated in limbs denervated at various stages and at successive intervals after denervation. Both forelimbs were amputated but only one side was denervated, through the brachial plexus, the other serving as a control. If denervation was carried out before the blastema became vascularised, the blastema did not become vascularised during the following 2 weeks whereas the control limbs regenerated normally (Fig. 2b and c). Denervation at the time when the

blastema begins to become vascularised, or later, did not appear to have gross effects on vascularisation but the resultant blood vessels tended to be thicker and the fine dermal network was often absent.

These results are consistent with our hypothesis that vascularisation of the blastema is dependent on the presence of nerves and that vascularisation plays a crucial role in normal regeneration. We can thus envisage the following interactions in regeneration. After amputation the retraction of the dermal vasculature results in an avascular region at the end of the stump. It is this region which undergoes dedifferentiation and gives rise to the blastema. We suggest that the blastema will not grow unless it becomes vascularised and that this vascularisation requires the presence of nerves. This accounts for the behaviour of limbs denervated at an early stage of regeneration. Denervation at stages when the blastema is already vascularised should have no effect on regeneration, unless the continued presence or further growth of the vessels is still nerve dependent. In fact the reduction in growth is associated with a reduction in vascularity. Here, muscle is more likely to be affected than cartilage, and histological investigations have shown this to be so¹⁰. Our hypothesis requires that limbs denervated very early should develop to the stage of a small avascular blastema and this is what both we and Revardel and Chapron¹¹ have found (Fig. 3). Our interpretation also explains why the effects of denervation are nonspecific and simply result in a general

angiogenesis and whether their effect is on the growth and sprouting of vessels themselves, or on tissues they invade. What is clear, is that blood supply and angiogenesis may play a crucial role in limb regeneration.

decrease in cell division and macromolecular synthesis at all stages. Moreover, the transitory increase in cell division and macromolecular synthesis immediately after denervation⁶ could be due to vasodilation caused by denervation. Blood supply may also be involved in the dedifferentiation of stump tissues. Dedifferentiation occurs in the avascular tip and we have shown that bone regression of about 0.5 mm occurs⁸ and this is similar in depth to the avascular region. Revardel and Chapron¹¹ have also emphasised the correlation between dedifferentiation and avascularity. It is also possible that the effects of X irradiation on regenerating limbs are in part a result of effects on the blood vessels.

The idea that blood supply is important in regenerative processes is not new and has been invoked in relation to compensatory hypertrophy of organs such as liver and lung¹²; the novel feature suggested here relates to the role of nerves. While all the above makes our suggestion plausible it must be emphasised that it in no way proves it: it is in fact disconcerting that we have not been able to find any reports relating nerves to angiogenesis in other systems. If we are correct, however, one may begin to consider how nerves could affect

Permeability of solutes through biological membranes measured by a desorption technique

THE influence of molecular structure of a solute on its permeation through biological membranes has been evaluated by various methods^{1–4}. For permeation of a solute across a membrane of thickness, h , the permeability coefficient, P , can be expressed in terms of the membrane-solution partition coefficient (K_m) and the diffusion coefficient in the membrane (D):

$$P = K_m D / h \quad (1)$$

We now present a further method, based on a desorption technique, in which the diffusivity of a solute in a membrane and its membrane-solution partition coefficient can be determined directly. A similar technique has been used in studies of vapour diffusion in polymers⁵. Biological material, initially equilibrated with an aqueous concentration of solute, is immersed in distilled water. The rate at which a solute is desorbed from the membrane reflects its diffusivity whereas the amount desorbed is used in the estimation of the membrane-solution partition coefficient of the solute.

The approach has several advantages. (1) Direct estimation of membrane-solution partition coefficients (which are not affected by the irreversible sorption of the solute on the membrane) avoids analysis of permeation results by organic solvent-water partition coefficients⁶; (2) the diffusivities of different solutes in a membrane are indicated by the rates of desorption of the solutes and may be compared without estimates of membrane thickness; (3) the results of this technique are relatively insensitive to the presence of holes or tears in the membrane; and (4) the presence of complications such as aqueous boundary layer effects⁷ or additional routes of solute penetration^{1–4} may be ascertained by comparison of the permeability estimates from permeation⁸ and desorption experiments.

The several treatments of diffusion (random walk, solution of formal diffusion equations, Eyring's theory and so on) are compatible and lead essentially to the same solution⁹. Crank¹⁰ presented two solutions for the diffusion of a solute into or out of a semi-infinite slab with boundary conditions of in-

stantaneous equilibrium of sorbent entities at the surfaces. The solutions are given as:

$$\frac{M_t}{M_\infty} = 1 - \frac{8}{\pi^2} \sum_{n=0}^{\infty} \frac{1}{(2n+1)^2} \exp \left[-\frac{(2n+1)^2 \pi^2 D t}{h^2} \right] \quad (2)$$

and

$$\frac{M_t}{M_\infty} = 4 \left(\frac{D t}{h^2} \right)^{1/2} \left[\frac{1}{\pi^{1/2}} + 2 \sum_{n=1}^{\infty} (-1)^n \operatorname{ierfc} \left(\frac{nh}{2(Dt)^{1/2}} \right) \right] \quad (3)$$

where M_t is the amount of solute sorbed or desorbed at time t , M_∞ is the equilibrium amount sorbed or desorbed after infinite time, D is the diffusion coefficient of the solute in the membrane and h is the membrane thickness.

These equations are valid for the desorption of a solute from a biological membrane providing several assumptions are satisfied. (1) There is a single solute in true solution and initially uniformly distributed in the membrane; (2) the composition of the membrane is unaltered during the diffusion process; (3) the diffusion coefficient of the solute is independent of time and position in the membrane, and (4) the solute is desorbed into a well stirred infinite sink which does not affect the desorption process.

If the solute is desorbed from a membrane into a well stirred sink, a contribution to M_t and M_∞ is given by M_i the solute present in solution adhering to the surfaces of the membrane. This may be reduced by rinsing the surfaces of the membrane. In this study the spectrophotometric analytical procedure has introduced a lag time (τ).

Addition of the parameters τ and M_i to the equations yield:

$$M_t = M_\infty - \frac{8(M_\infty - M_i)}{\pi^2} \times \sum_{n=0}^{\infty} \frac{1}{(2n+1)^2} \exp \left[\frac{(2n+1)^2 \pi^2 D (t - \tau)}{h^2} \right] \quad (4)$$

and

$$M_t = M_i + 4(M_\infty - M_i) \left(\frac{D(t - \tau)}{h^2} \right)^{1/2} \times \left[\frac{1}{\pi^{1/2}} + 2 \sum_{n=1}^{\infty} (-1)^n \operatorname{ierfc} \left(\frac{nh}{2D^{1/2}(t - \tau)^{1/2}} \right) \right] \quad (5)$$

The amount desorbed (M_t) is nonlinear with time (t) with four unknown parameters τ and M_∞ , M_i and D/h^2 . Since approximate values of τ and M_∞ are known, estimates for M_i and D/h^2 may be found using an approximation of equation (5) which applies over short times:

$$M_t = M_i + 4(M_\infty - M_i) \left(\frac{D(t - \tau)}{\pi h^2} \right)^{1/2} \quad (6)$$

With these initial estimates, an iterative nonlinear least squares regression program (NONLIN, C. M. Metzler, Upjohn, which uses a modification of Hartley's¹ method to estimate the parameters of a system of nonlinear functions) was used. The best parameter values were found by minimising equation (7) until convergence (where lack of change in sums of squares (SS) is the convergence criterion):

$$SS = \sum_{i=1}^n \left(M_{t_i \text{ observed}} - M_{t_i \text{ predicted}} \right)^2 \quad (7)$$

Fig. 1 Arrangements for monitoring the desorption of a compound from a biological membrane. Compound is desorbed from the membrane held in mesh support, S, into thermostated beaker, B, containing distilled water and stirred with a magnetic stirrer, M. The desorbing solution is pumped at a constant rate through the peristaltic pump, P, directly into a thermostated flow-through spectrophotometer cell, C, back into the beaker. M_t , the amount desorbed at time, t , is estimated from the observed absorbance, A_t , of the desorbing solution. (For desorption into 60 ml, suitable absorbance values have been obtained using 5–25 mg wet weight of stratum corneum.)

Equation (4) was evaluated satisfactorily using four exponential terms and additional terms gave no improvement. A polynomial was used to evaluate the error function series and the summation term in equation (5) was evaluated until the change in its value was less than 1×10^{-5} , which is insignificant compared with $1/\pi^2$. A typical regression curve for a set of data is shown in Fig 2. Parameter estimates are independent of whether equation (4) or (5) is used.

The solute membrane-solution partition coefficient (K_m) may be evaluated from the expression

$$K_m = \frac{(M_\infty - M_i)}{W_m C_s}$$

where W_m is the weight of the membrane, C_s is the concentration of the solute in the solution with which the membrane was equilibrated and $(M_\infty - M_i)$ is the amount of solute desorbed. Some stratum corneum-water partition coefficients are shown in Table 1.

A Collander-type plot¹² of the stratum corneum-water partition coefficient (K_m) against the octanol water-partition coefficient (K_o) shows good correlation (Fig. 3). The values of D/h^2 are indicative of the diffusivities of solutes in a membrane and those for several phenols are listed in Table 1. Good reproducibility of K_m and D/h^2 was found on repeated use of the same membrane, the use of samples of stratum corneum taken from the same area of a cadaver, and initial equilibration of the membrane with different concentrations of solute.

Fig. 2 Typical regression curve for observed absorbance against time following desorption of a solute (*p*-cresol) from hydrated stratum corneum. Correlation coefficient = 0.998; $(D/h^2) \times 10^3 = 1.46 \pm 0.08 \text{ s}^{-1}$; $(A_\infty - A_i) = 0.117 \pm 0.003$; $A_i = 0.010 \pm 0.001$; $\tau = 7.15 \pm 0.15 \text{ s}$; sum squared observations = 0.264; sum of squared deviations (SS) $\times 10^5 = 0.500$.

Table 1 Desorption data for human stratum corneum

Solute	$K_m \pm \text{s.d.}$	$D/h^2 \pm \text{s.d.}$ ($\text{s}^{-1} \times 10^3$)	Regression correlation coefficient
Benzyl alcohol	5.0 ± 0.2	0.88 ± 0.04	0.997
Phenylethyl alcohol	5.4 ± 0.3	1.01 ± 0.09	0.992
Phenol	5.4 ± 0.2	0.98 ± 0.05	0.996
<i>p</i> -Cresol	10.3 ± 0.2	1.46 ± 0.08	0.998
<i>m</i> -Cresol	10.4 ± 0.3	1.30 ± 0.07	0.995
<i>o</i> -Cresol	10.5 ± 0.2	1.21 ± 0.08	0.994
<i>p</i> -Bromophenol	27.7 ± 0.4	1.10 ± 0.06	0.997

The wet weight of stratum corneum (separated from other epidermal layers¹⁴) may be estimated by a dehydration technique¹⁶. Combination of D/h^2 , h , and K_m may be used to estimate P using equation (1).

This technique seems to be applicable to studies of drug absorption, pharmaceutical formulation and membrane transport. In the study of drug administration and disposition, the diffusivity and partition behaviour of solutes in various mammalian tissues are of interest.

Fig. 3 Collander-type plot of stratum corneum-water partition coefficient (K_m) against octanol-water partition coefficient (K_o)^{3,13} for some non-electrolytes. Compounds are referred to as follows: 1, methanol; 2, ethanol; 3, propanol; 4, butanol; 5, benzyl alcohol; 6, pentanol; 7, phenylethyl alcohol; 8, phenol; 9, hexanol; 10, *p*-cresol; 11, *m*-cresol; 12, *o*-cresol; 13, *p*-bromophenol; 14, heptanol. (Stratum corneum-water partition coefficients are from Table 1 and ref. 4.)

Corneal epithelium (50 μm), stratum corneum (10 μm) and dermis (1,000 μm) are of suitable thickness for evaluation by this technique. For very thin membranes, the technique would have only limited application because desorption would occur rapidly. Since spectroscopy, radiotracer methods, conductometry and so on are suitable analytical methods for this technique, a wide range of solutes may be investigated.

We thank Dr D. E. Moore for helpful suggestions.

Macrophages on intrauterine contraceptive devices produce prostaglandins

THE mechanisms whereby intrauterine contraceptive devices (IUDs) exert their anti-fertility effects remains unestablished¹. The involvement of prostaglandins (PGs) is being investigated²⁻⁵, although alternative mechanisms have been proposed (for example, phagocytic and other actions of macrophages^{6,7}). Although the relative contributions of macrophages and PGs to the anti-fertility actions of IUDs remains uncertain, it is clear that introduction of the IUD into the endometrial cavity results in an infiltration by neutrophils and macrophages⁸ as well as increased PG levels in uterine venous blood in animals^{9,10}. While investigating the role of mediators of chronic inflammation we have demonstrated that the macrophage is a potent source of PGE₁¹¹, and since the macrophage is the predominant cell adhering to the IUD⁸ we have considered the possibility that such cells act as a source of PGs.

IUDs routinely removed at out-patient clinics were incubated in 10-20 ml Eagle's MEM supplemented with 10% heat-inactivated foetal calf serum for 24 h at 37 °C in an atmosphere of 5% CO₂ in air. After incubation, supernatants were centrifuged and stored at -20 °C for PG assay. Cells were removed from the devices by treatment with 0.01% trypsin for 5 min at 37 °C, and total cells counted with cell viability established by dye exclusion. Differential cell counts were made on cell smears stained with Toluidine blue, Papanicolaou or Giemsa stains. PG concentrations were determined by radioimmunoassay¹² using sheep antibodies to PGE₂/bovine serum albumin and to PGF_{2 α} /bovine serum albumin. Anti-PGE₂ antiserum did not distinguish PGE₁ from PGE₂ (cross reaction 100%); the relative cross reactivities of other PG groups, based on the amount of unlabelled PG required to displace 50% antibody-bound label, were PGF_{2 α} (13%), PGA₂ (1.3%) and PGB₂ (< 0.6%). Anti-PGF_{2 α} antiserum (cross reaction of PGF_{2 α} 100%) also cross reacted with PGF_{1 α} (27%), but only slightly with PGE₂ (< 0.13%), PGA₂ (< 0.013%) and PGB₂ (< 0.016%). Results were expressed as PGE₂ or PGF_{2 α} equivalents. Seventeen IUDs have been examined so far including eleven of the type Gravigard Copper 7 (Searle, UK), four Lippes loops (Ortho, USA), and two Dalkon shields (Robins, USA). In all cases significant PG activity has been detected in culture fluids collected at 24 h (Table 1). The time course of PG production was determined for several devices

Table 1 PG production by IUDs in *in vitro* culture

IUD (n)	Total WBC ($\times 10^7$) mean \pm s.e.m.	Prostaglandin-like activity in culture fluid (ng PG eq. per 10^7 cells per 24 h) mean \pm s.e.m.	
		PGE ₂	PGF _{2α}
Copper 7 (11)	2.25 ± 0.67	190 ± 52	464 ± 110
Lippes loop (4)	2.00 ± 0.78	161 ± 107	287 ± 198
Dalkon shield (2)	7.50 ± 2.9	92 ± 38	249 ± 37

IUDs cultured in Eagle's MEM and 10% foetal calf serum for 24 h at 37 °C in a 5% CO₂ in air atmosphere. Cells removed by centrifugation and counted. Supernatants stored for assay. 50- μl volumes assayed for PGE₂ and PGF_{2 α} activities by radioimmunoassay. WBC, White blood cells; n, number of IUDs.

Fig. 1 Time course of prostaglandin (PG) generation for a Copper 7 IUD. The ordinate depicts the concentration of PGE₂ (○) and PGF_{2α} (●) expressed as ng per 10⁷ cells as determined by radioimmunoassay.

and Fig. 1 shows a time course for PGE₂ and PGF_{2α} production by a Copper 7. In general, the PG production correlated with the total cell number on the IUD, and production of PGF rather than PGE predominated in 16 of the 17 devices examined. This contrasts with the guinea pig macrophage where the PGFs constitute less than 10% of the PG activity¹¹ and may relate to the close proximity of macrophages with the copper component of the Copper 7 device, since copper modifies PG production in other situations^{13,14}, or to the regulatory actions of steroid hormones on macrophages¹⁵. Cells identified morphologically as macrophages were the principal cell type on each device. Substantial numbers of neutrophils were observed on some devices but were not associated with enhanced PG production, and in view of the comparative ineffectiveness of neutrophils in PG generation compared with macrophages^{11,16-18}, it seems unlikely that the neutrophil is the source of the PG activity associated with IUDs.

These observations relate two lines of evidence concerning the suggested mode of action of IUDs by showing that the macrophages adherent to IUDs are a likely source of the increased PG concentrations associated with these contraceptive devices. Because the macrophage is such a potent source of prostaglandin, it is worth considering this cell as a source of uterine prostaglandins. Macrophages show cyclical changes in activity in response to altered circulating steroid levels during the oestrous cycle¹⁵, and thus may provide a mechanism whereby the changes in steroid levels can determine the variations in PG production by the uterus during the oestrous cycle¹⁹.

Cytocidal and cytostatic effects of activated peritoneal leukocytes

MACROPHAGES seem to be of importance in both immunologically specific and nonspecific resistance to neoplastic cells¹⁻¹⁰. It has been proposed¹¹⁻¹³ that activated macrophages are significant effectors in the elimination of tumour cells at sites of delayed hypersensitivity reactions induced by chemical haptens, microbial antigens or lymphokines¹³⁻¹⁸. Immunologically specific elimination of neoplastic cells by macrophages may be mediated by tumour-specific antibodies^{7,10,19,20}. Such antibodies may also confer specificity to macrophages activated by nonspecific stimulation. Besides specificity which may be imparted by antibodies, activated macrophages seem to possess an inherent recognition mechanism which permits selective cytotoxicity towards certain categories of cells, including tumour cells^{11,21-23}.

Although it seems that activated macrophages are cytotoxic towards neoplastic cells^{8,9,11,12,21-23}, there are seemingly conflicting reports on the effects of activated macrophages on cells established from normal tissues. In a number of *in vitro* studies^{11,21-23} insignificant or no effects of activated mouse or rat peritoneal macrophages were noted on fibroblasts of normal adult or embryonic tissue origin. Normal mouse embryonic fibroblasts have, however, been reported to be destroyed by peritoneal leukocytes of nonspecifically stimulated mice²⁴. Our present results offer a possible reconciliation of these differing observations. Rat embryonic cells of a low *in vitro* passage number and a concomitant high rate of replication were found to be susceptible to cytotoxic effects of peritoneal leukocytes of nonspecifically stimulated syngeneic rats. In contrast, embryonic cells of a higher *in vitro* passage number and a lower rate of replication were relatively resistant to such leukocyte preparations.

Rats of the inbred Fischer strain were used. Cells of whole rat embryos close to term were stored in liquid nitrogen. In any one experiment the embryo cells were from the same batch in the second (FE₂) or the sixth (FE₆) *in vitro* passage. Sarcomas were induced by injection of newborn rats with polyoma virus. Cells of these tumours (PYT) were established *in vitro*. Peritoneal leukocytes were collected by intraperitoneal lavage of rats which 48 h previously had received an intraperitoneal injection of 50 µg PPD (purified protein derivative of tuberculin). The differential counts of the peritoneal cells were: large mononuclear cells, 65-75%; small lymphocytes, 10-15%; neutrophils,

Table 1 Effect of challenge of PYT, FE₂ and FE₆ cells with peritoneal leukocytes from PPD-stimulated Fischer rats

Culture combination	Target cells per dish ($\times 10^3$) at time 0	Target cells per dish ($\times 10^3$) at 48 h	Unchallenged cultures (%)	Growth index
PYT+M	241; 217	1,747; 1,652	100	7.5
PYT+SP		75; 62	4; 4	
FE ₆ +M	115; 105	188; 182	100	1.7
FE ₆ +SP		144; 141	77; 76	
FE ₂ +M	140; 157	552; 545	100	3.7
FE ₂ +SP		138; 136	25; 25	

Duplicate cultures of PYT or rat embryo cells in 2nd or 6th *in vitro* passage were challenged with peritoneal leukocytes (SP) of a PPD-stimulated rat. Companion cultures received medium (M) only. After 48 h the cells were collected and the target cells counted electronically. The growth index is the ratio between cell counts at 48 h and time 0 of unchallenged cultures.

4–12%; eosinophils, 4–8%, mast cells, 4–8%. Cytotoxicity of the peritoneal leukocytes towards the various target cells was tested as follows. Target cells were seeded in 35-mm round plastic dishes 24 h before use and incubated at 37 °C in a water-saturated atmosphere containing 5% CO₂. On the day of initiation of an experiment (time 0) the culture fluid was removed and replaced with 3 ml of either fresh medium or a suspension of 2×10^6 peritoneal leukocytes. After a further 48-h incubation the cells of duplicate cultures of the various experimental groups were collected and the target cells counted electronically. These procedures, as well as the basis for the use of PPD stimulation of the peritoneal leukocyte donors, have been described previously^{23,26}.

In a series of four experiments, cultures of PYT, FE₆ and FE₂ cells were challenged with peritoneal leukocytes from PPD-stimulated Fischer rats. A set of companion cultures remained unchallenged. The data from one such experiment are presented in Table 1; comparable figures were obtained in the other three experiments. The peritoneal leukocytes substantially reduced the numbers of the sarcoma cells (Table 1). The final relative counts of these cells were of the order of 4% of the unchallenged companion cultures and their absolute numbers were significantly lower than the time zero counts. In contrast to the sarcoma cells, FE₆ embryo cells increased in numbers when cultured with the peritoneal cells, reaching 76–77% of the cell numbers of the unchallenged controls. The numbers of the FE₂ embryo cells, on the other hand, remained essentially stationary when challenged with the same peritoneal leukocyte preparation. These findings suggest that susceptibility to the cytotoxicity of activated peritoneal macrophages is not solely an attribute of neoplastic cells. The effect of the activated peritoneal leukocytes on the low passage embryonic cells, however, had more the character of growth inhibition than the frankly cytotoxic effect on the sarcoma cells.

Previous observations^{11,21–23} have indicated that susceptibility or resistance of cells to the cytotoxicity of activated peritoneal leukocytes is not likely to be related to recognition of target cell antigenic determinants, nor is it a consequence of non-specific culture conditions, such as crowding of cells or metabolic depletion. Table 1, together with other findings^{23,26}, suggests an association between growth rate of normal embryo cells and susceptibility to the cytotoxicity of nonspecifically activated peritoneal leukocytes. Of possible relevance to this association is the agglutinability of non-transformed 3T3 mouse cells by plant lectins only when the cells were in mitosis²⁷. The same 3T3 cells after transformation by polyoma virus, however, were agglutinated by the lectins at any time, irrespective of their position in the growth cycle. It seems therefore that transformed cells continuously exhibit surface properties which normal cells only exhibit when they are in mitosis. Such or similar properties are possibly also reflected in the differential cytotoxic effects reported here. The mechanism of the cytotoxic and the cytostatic effects of activated macrophages may not be fundamentally different. In both situations

destruction of susceptible target cells is likely to take place. The final outcome of macrophage interactions with normal cells in terms of changes in target cell numbers in given culture conditions with respect to macrophage and target cell densities, however, may depend on the relative numbers of target cells in mitosis.

An alternative interpretation of the difference in susceptibility of the high and low passage embryonic cells is selection of a relatively resistant population during *in vitro* cultivation. When initially prepared, embryo cells represent a very heterogeneous population. Certain segments of this population may be susceptible, whereas others may be resistant to the cytotoxicity of activated peritoneal leukocytes. After a number of passages *in vitro* a change in the proportions of these segments may take place resulting in a population with a higher overall resistance.

Neoplastic cells may have certain properties in common with embryonic cells. An additional consideration, therefore, is that the apparent difference in susceptibility of embryo cells of low and high *in vitro* passage number could be attributable to cellular differentiation during cultivation *in vitro*. At the time of isolation from the embryos, the cells may exhibit certain surface properties which are lost during growth *in vitro* as a sequel to differentiation. Although macrophages are present in noticeable numbers in some embryonic tissues at certain stages of differentiation²⁸ a possible relationship of the observations reported here to a specific function of macrophages in embryonic development is at present conjectural.

Partial characterisation of Ia antigens on murine thymocytes

GENES controlling specific immune responsiveness at the level of activation of the thymus derived (T) lymphocyte, and collaboration of these cells with lymphocytes derived from the bursal equivalent (B lymphocytes), have been shown to be linked to the major histocompatibility complex (MHC) in many species¹. The mechanism of action of these genes is not understood, and it has been postulated that they represent structural genes for a non-immunoglobulin receptor for antigen on T lymphocytes².

In the mouse, the immune response (Ir) genes linked to the MHC have been mapped to the I region of the H-2 complex³. The I region has recently been shown to be associated with antigenic molecules (Ia antigens) expressed predominantly on B lymphocytes, but also on several non-lymphoid populations. The Ia antigens might represent products of the Ir genes. Paradoxically, in view of the strong evidence for the expression of the MHC-linked Ir genes in T cells¹, whether or not Ia antigens are expressed on T cells has been a matter of some controversy⁴⁻¹⁰. Because of the continuing debate on the nature of the T-cell receptor^{11,12}, the question of the expression of Ia antigens on T lymphocytes is of considerable importance. Previous work from this and other laboratories has indicated that Ia antigens can be detected on T lymphocytes^{8,10} and T lymphoma cells⁹. Ia antigens from several cell sources have also been partially characterised by immunochemical techniques^{8,13,14}, although so far attempts to isolate Ia antigens from thymocytes have proved unsuccessful. In this report, we demonstrate the specific immunological precipitation of Ia antigens from extracts of surface radioiodinated thymocytes.

The outer membranes of thymocytes from A.TL mice were radioiodinated by the lactoperoxidase technique¹⁵ and extracted with the non-ionic detergent Nonidet P-40 (NP-40). The cell extract was then held with A.TH anti-A.TL (anti-I^a; experimental) serum or A.TL anti-A.TH (anti-I^a; control) serum, followed by rabbit anti-mouse IgG serum. The resulting precipitates were centrifuged, washed, and analysed by polyacrylamide gel electrophoresis in the presence of sodium dodecyl sulphate (SDS) and mercaptoethanol¹⁶.

As shown in Fig. 1, radioiodinated surface immunoglobulin was not detected in these conditions. It has previously been shown that NP-40 extraction does not allow clear demonstration of immunoglobulin on murine thymocyte membranes, although it is very efficient in extraction of immunoglobulin from B lymphocytes¹⁷. In our first experiments, a large peak of radioactivity migrating a little ahead of the γ chain in both control and experimental precipitates was found. It was precipitable by IgG-anti-IgG, IgM-anti-IgM and fowl IgG-anti-fowl IgG complexes, and was invariably present in comparable amounts in control and experimental precipitates. This peak has been observed elsewhere^{18,19}, and was considered to be a component which binds to antigen-antibody complexes. In subsequent experiments, this component was depleted by a factor of approximately five by preliminary precipitation with fowl IgG and rabbit anti-fowl IgG (legend to Fig 1). In addition, a small but unequivocal peak of radioactivity migrating just behind the light chain standard was consistently observed in the experimental (A.TH anti-A.TL) but not in the control (A.TL anti-A.TH) precipitates. Identical results were obtained in three independent experiments, and the peak was also clearly visible in autoradiographs. This peak corresponded to a molecular weight of approximately 30,000, although determination of molecular weight by polyacrylamide gel electrophoresis must be made with some caution, as carbohydrate differences considerably influence mobility²⁰. A third peak, corresponding to an R_f of approximately 0.05, was seen in some experiments. It was rather variable in size, but was

Fig. 1 Thymuses from 6-week-old female A.TL mice were removed, taking care to avoid removal of the parathyroid lymph nodes, and teased gently through a fine sieve into phosphate-buffered saline (PBS). Dead cells and clumps were removed by the method of von Boehmer and Shortman²¹. Cells were surface radioiodinated with ¹²⁵I as follows. To five plastic centrifuge tubes, each containing 10⁷ cells in 30 μ l PBS, was added 10 μ l lactoperoxidase (0.25 mgml⁻¹), 5 μ l carrier free ¹²⁵I sodium iodide (0.05 mM, 100 μ Ci μ l⁻¹), and 10 μ l 8.8 mM H₂O₂. Cells were held at 30 °C for 5 min, pooled, and washed once with 5 ml PBS. They were then extracted with 1% NP-40 in PBS (3.5 ml) at room temperature for 1 h, centrifuged, and the supernatant dialysed against PBS for 4 h at 4 °C. The extract was then centrifuged at 10,000g for 30 min, and the supernatant divided into 200- μ l aliquots, to which were added 100 μ l rabbit anti-fowl IgG (absorbed against mouse immunoglobulin) and 100 μ l of 0.1 mgml⁻¹ fowl IgG. The mixture was held at 37 °C for 1 h, and 4 °C overnight. It was then centrifuged at 10,000g for 20 min, and the precipitates discarded. To each tube was added 2 μ l A.TH anti-A.TL serum, or A.TL anti-A.TH serum prepared as previously described⁶. Both antisera were extensively absorbed for autoantibodies before use. The extracts were incubated at 37 °C for 1 h, and then an appropriate amount of rabbit anti-mouse IgG serum added quantitatively to precipitate the mouse IgG. A further incubation was performed at 37 °C, and the tubes left at 4 °C overnight. The precipitates were washed four times, and then boiled in a buffer solution containing 5% mercaptoethanol and 3% SDS, and analysed by discontinuous polyacrylamide gel electrophoresis as described by Laemmli and Favre¹⁶. The total concentration of polyacrylamide was 10%, and the concentration of bisacrylamide was 0.25%. Gels were 10 cm long and 5 mm in diameter. The precipitated material from 5 \times 10⁷ cells was ultimately distributed among four gels (two control and two experimental), each gel thus representing material from 1.25 \times 10⁷ cells. Gels were sliced transversely into 2-mm sections and counted in a Packard gamma counter, or sliced longitudinally and processed for autoradiography. Calibration of molecular weights was done by running parallel gel electrophoresis of proteins of known molecular weights. ●, A.TH anti-A.TL serum; ○, A.TL anti-A.TH serum.

always of similar height in experimental and control precipitates. This peak may represent high molecular weight aggregates.

It is unlikely that the 30,000 molecular weight peak is due to the presence of small numbers of B lymphocytes in the thymocyte cell suspension. The fraction of A.TL thymus cells with high density surface immunoglobulin was found to be less than 0.5%, as assessed by autoradiography using polyspecific radioiodinated anti IgM serum, and we are unable to detect Ia extracted from this number (6 \times 10⁴) of B lymphocytes. Further, it has been demonstrated that the TCA precipitable radioactivity incorporated into NP-40 extractable immunoglobulin on B cells following surface iodination is considerably more than that incorporated into B cell Ia antigens¹⁴, yet no radioactivity corresponding in mobility to immunoglobulin chains was seen (Fig. 1). Thus, the relative amounts of Ia and immunoglobulin do not support the hypothesis that the detected Ia was obtained from B cells.

There are several possible reasons for our ability to extract and identify Ia from thymocytes. First, and probably of prime importance, is the titre and specificity of the anti-Ia serum used. The A.TH anti-A.TL serum was of very high titre (1 : 2,000

against spleen cells by semi-microcytotoxicity and 1 : 10,000 by microcytotoxicity tests using rabbit complement), and has been shown lightly but specifically to label 10–20% of thymocytes in autoradiographic experiments⁸. Fathman *et al.* (C. G. Fathman, J. L. Cone, S. O. Sharrow, H. Tyrer, and D. H. Sachs, personal communication) have also shown, using the fluorescence activated cell sorter, that a subpopulation of thymocytes bears Ia antigens in small amounts. Many anti-Ia sera, usually of much lower titre, only react with B cells⁴. Second, labelling by surface radioiodination, rather than biosynthesis using radiolabelled amino acids, allows a far better signal to noise ratio, since radioactivity is confined to the area of interest. Third, optimal iodination conditions and excellent cell viability, both before and after iodination, were found to be essential for good results.

Our results are consistent with the serological data indicating that Ia antigens are present in large amounts on B lymphocytes and in much smaller amounts on T lymphocytes^{8,10}. The sera used in our studies potentially recognise the products of all I subregions. In view of the increasing evidence for heterogeneity of I region products, future work must concentrate on the use of sera of more restricted specificity, and attempt to understand the possible relationships between the Ia antigens and products of the immune response genes.

We thank Drs J. L. Atwell and D. Haustein for valuable discussions. This work was supported by research grants from the US Public Health Service, the American Heart Association and the National Health and Medical Research Council of Australia.

Isolation and properties of a murine spleen cell Fc receptor

MURINE and human bone marrow-derived (B) lymphocytes have a cell surface-bound receptor for antibody complexed to antigen. Heat-aggregated immunoglobulin complexes will also bind to this receptor, and the binding is specifically mediated by means of the Fc portion of the IgG molecule^{1–3}. So far, the only function ascribed to the Fc receptor is in the antibody-dependent lymphocyte-mediated cytotoxicity reaction⁴. A recent report has indicated, however, that the Fc receptor is identical to or closely associated with the Ia antigens on the B-cell membrane⁴. The Ia antigens are alloantigens coded for by the immune response region of the major histocompatibility

complex⁵ and if indeed these antigens and the Fc receptor are identical, this would reveal a role for the receptor in several aspects of the immune response⁶.

To gain insight into the possible relationship between the Fc receptor and the Ia antigens it seems mandatory to isolate and characterise chemically these molecules. As a first step towards this goal we have isolated an Fc receptor from mouse spleen cells and here report some of its properties.

Crude membrane fractions were isolated from 400 A/Sn mouse spleens. The membrane fraction was suspended in 0.02 M Tris-HCl buffer, pH 7.4, containing 80 mM EDTA and 50 mM β -mercaptoethanol at a final protein concentration of 10 mg ml⁻¹. Soluble macromolecules were recovered after centrifugation of the incubation mixture at 100,000g for 60 min. The supernatant was subsequently subjected to affinity chromatography on a column of Sepharose 4B to which heat-aggregated human IgG had been covalently attached. The column was eluted as described⁷. The eluted macromolecules were labelled with ¹²⁵I and subjected to sodium dodecyl sulphate (SDS)–polyacrylamide gel electrophoresis⁷ together with suitable marker proteins of known molecular weight. Figure 1 depicts a typical result of an electrophoretic separation in SDS of ¹²⁵I-labelled macromolecules with affinity for heat-aggregated IgG. Three types of polypeptide chains with apparent molecular weight of approximately 65,000, 18,000 and 15,000 were clearly distinguishable. Figure 1 also demonstrates that the 65,000-dalton component as well as one (or both) of the two smaller polypeptide chains contained sialic acid as evidenced by radioactive labelling with ³H-sodium borohydride⁸. The three ¹²⁵I-labelled polypeptide chains were extensively reduced and alkylated in 6 M guanidine hydrochloride and subjected to gel chromatography on a column of Sepharose 6B equilibrated with the same solvent. The elution

Fig. 1 SDS–polyacrylamide gel electrophoresis of ¹²⁵I-labelled (a) and ³H-sodium borohydride-treated (b) highly purified mouse spleen cell Fc receptor. The macromolecules were passed over a Sepharose 4B-coupled heat aggregated IgG column. Material attached to the column was eluted with 0.05 M sodium citrate buffer, pH 3.0, containing 0.5 M NaCl. The recovered protein, labelled with ¹²⁵I or ³H, was introduced into sialic acid residues. H and L denote the migration positions of marker heavy and light chains of IgG. The marker dye was bromophenol blue (BFB).

Fig. 2 SDS-polyacrylamide gel electrophoresis of ^{125}I -labelled highly purified mouse spleen cell Fc receptor. *a*, The material was the same as shown in Fig. 1 but the electrophoresis was performed after 2 d incubation at 4°C . *b*, The 65,000-dalton component after thermolysin. The ^{125}I -labelled 65,000-dalton component was mixed with bovine IgG and digested with thermolysin (20% w/w) for 10 min at 37°C . —, Material before proteolysis; — — —, after thermolysin digestion.

positions of the ^{125}I -labelled molecules corresponded to apparent molecular weights of 65,000, 14,000 and 13,000, respectively. The higher molecular weight values obtained by SDS-electrophoresis are consistent with the presence of carbohydrate in the Fc-receptor proteins. This strongly suggests that each component represents a single polypeptide chain.

The specificity and efficiency of the isolation procedure was investigated by incubating ^{125}I -labelled samples of the crude membrane protein and of the breakthrough material from the affinity chromatography column with antigen-antibody complexes. The antigen-antibody complexes were formed from bovine serum albumin (BSA) and a heat-inactivated rabbit antiserum against BSA. After 30 min of incubation, precipitates were collected by centrifugation, extensively washed and subjected to SDS-polyacrylamide gel electrophoresis. The electrophoreses revealed that the starting material contained the same three components which had been isolated by affinity chromatography, but the smaller polypeptide chains were now the dominant components. The absorption on to the affinity chromatography column was very efficient since the breakthrough material recovered from the column contained negligible amounts of protein reacting with the antigen-antibody complexes.

Similar experiments showed that the isolated Fc-receptor components retained their affinity for antigen-antibody complexes even after desorption from the affinity chromatography column.

The three polypeptide chains were encountered in all highly purified preparations. On standing at 4°C for a few days additional components arose, presumably because of the presence of proteolytic activity in the preparations. Figure 2*a* depicts an SDS-polyacrylamide gel electrophoresis of the same material as shown in Fig. 1, but after 2 d at 4°C . It can be seen that in addition to the 65,000, 18,000 and 15,000-dalton components, new material appeared in the apparent molecular weight positions 30,000 and 45,000, respectively. This result

suggested that the 18,000 and 15,000-dalton components were degradation products of the 65,000-dalton molecule. That this indeed is the case was demonstrated by subjecting the isolated 65,000-dalton component to thermolysin digestion. Figure 2*b* shows that such treatment gave rise to three additional polypeptide chains. The main component had an apparent molecular weight on SDS-polyacrylamide gel electrophoresis of about 30,000, whereas the two smaller components had molecular weights of 18,000 and 15,000, respectively. Solubilisation of membrane macromolecules by treatment with NP-40 or by papain digestion usually gave Fc-receptor components with apparent molecular weights of about 30,000 and 15,000 as estimated on SDS-polyacrylamide gel electrophoresis. A common origin for the 65,000, 18,000 and 15,000-dalton components was also suggested by the immunological cross reactivity between the three polypeptide chains (L.K., L.R. and P.A.P., unpublished).

Rabbit antisera were raised separately against the 65,000-dalton material and the mixture of the 18,000 and 15,000-dalton components. Table 1 shows that such antisera reacted exclusively with B lymphocytes. That the antisera bound to the B-cell Fc receptor was documented in a separate experiment. Aggregated IgG was labelled with fluorescein isothiocyanate³ (FITC) and allowed to bind to spleen cells treated with various antibody IgG and (Fab')₂ fractions. Table 2 shows that intact antibodies of various specificities all impeded the binding of aggregated IgG provided they bound to the B-cell surface. This result is in agreement with previous findings⁹. When (Fab')₂ fragments, lacking the Fc portion, of these antisera were used, however, only those directed against the isolated 65,000-dalton and the 18,000–15,000-dalton components were effective (Table 2). The (Fab')₂ fragments against H-2^k were also effective in reducing the number of cells containing aggregated IgG. This antiserum retains its ability to abolish binding of aggregated IgG to B cells even after all measurable anti-H-2 alloantigen activity has been absorbed out on thymocytes of the relevant antigen type. It seems reasonable to conclude that the antiserum contains anti-Ia antibodies since similar results were obtained with a specific anti-Ia serum (Table 2)^{4,9}.

If the Fc receptor and the Ia antigens are physically associated

Table 1 Cell binding of antibodies against the 65,000-dalton polypeptide chain and against the mixture of the 18,000 and 15,000-dalton components

Cell source	Treatment*	Antiserum	Stained cells (%)
Spleen	—	65,000	44 ± 6
Spleen	—	18–15,000	42 ± 8
Spleen	anti-Thy1 2	65,000	86 ± 4
Spleen	anti-Thy1 2	18–15,000	81 ± 11
Lymph nodes	—	65,000	22 ± 2
Lymph nodes	—	18–15,000	20 ± 3
Spleen	—	Ig	42 ± 5
Lymph nodes	—	Ig	16 ± 6

The cells obtained from C₃H/He mice were adjusted to a final concentration of 5×10^7 cells per ml in Hanks' minimal essential medium (MEM) containing 2% bovine serum albumin. Samples of 50 μl were incubated with 5 μl antiserum of the appropriate specificity for 30 min at 4°C . The cells were washed twice with the medium, resuspended in 50 μl of fresh medium, and incubated with 5 μl of FITC-conjugated goat anti rabbit IgG (14 mg ml⁻¹) for another 30 min at 4°C . At the end of the incubation period, the cells were washed three times with the medium and examined in a Leitz Ortholux microscope equipped with a HBO 200-W lamp. Ploem-type vertical illuminator and immersion objectives were used. In each experiment 200 cells were scored for cell surface fluorescence.

*To 10^8 spleen lymphocytes 0.3 ml of an anti-Thy1.2 antiserum was added and incubation was allowed to proceed for 30 min at 4°C . The cells were washed twice in Hanks' MEM and resuspended in 5 ml of a 1/10-dilution of fresh rabbit serum absorbed on agarose. The medium also contained DNase (10 μg ml⁻¹). Incubation was at 37°C for 30 min. Cell debris was removed by extensive washing of the cells in Hanks' MEM, and the incubation with antibodies was carried out as described above.

Table 2 Effect of antibodies and antibody (Fab')₂ fragments of various specificity on the binding of aggregated IgG to murine spleen cells

Antibody specificity*	Pretreatment of cells with IgG (Fab') ₂ % Stained cells	
NRS	42 ± 4	41 ± 5
RBP	44 ± 6	41 ± 6
65,000	6 ± 1	8 ± 2
18-15,000	8 ± 2	7 ± 1
β ₂ μ	7 ± 3	41 ± 7
H-2K ^k	5 ± 2	6 ± 2
H-2K ^k (abs.)	7 ± 2	6 ± 3
Ia ^k	11 ± 3	8 ± 2

Spleen cells from C₃H/He mice were suspended in Hanks' MEM containing 2% bovine serum albumin at a final concentration of 5×10^7 cells per ml. Samples of 50 μl were incubated with 5 μl of the appropriate IgG on (Fab')₂ fraction (15 mg ml⁻¹). After incubation for 30 min at 4 °C, the cells were washed twice in Hanks' MEM. The cell concentration was again adjusted to 5×10^7 cells per ml and 50 μl of FITC-labelled aggregated human IgG (about 1 mg ml⁻¹ in phosphate-buffered saline containing 2% bovine serum albumin and 2 mM sodium azide) was added. After incubation for 30 min at 4 °C, the cells were washed twice and 200 cells were regularly scored for label. The data are the mean ± s.e.m. of three experiments.

* IgG was isolated from immune sera by a combination of sodium sulphate precipitation and Sephadex G-200 chromatography. (Fab')₂ fragments were prepared from the purified IgG by pepsin digestion. (Fab')₂ fragments were freed from remaining intact antibodies by gel chromatography on columns of Sephadex G-200. NRS denotes gamma globulin from a normal rabbit serum. RBP is a human serum protein. The anti-β₂-microglobulin (β₂μ) antiserum was raised in a rabbit against the human protein. This antiserum cross reacts with the mouse homologue. The anti-H-2K^k was raised in (BALB/c × C57BL/6) F₁ mice against A/Sn spleen cells. Absorption of this antiserum was accomplished with C₃H/He thymocytes. Before absorption the antiserum could kill more than 85% of spleen cells and thymocytes from the appropriate strains. After final absorption the antiserum was not cytotoxic against either cell type.

on the cell surface or indeed identical, antibody-induced redistribution and pinocytosis of the Fc receptor would simultaneously eliminate the Ia antigens from the cell membrane. Table 3 shows that although the Fc receptor could be capped away efficiently, no apparent redistribution of the Ia antigens could be demonstrated by the cytotoxicity technique. In a second set of experiments Ia antigens and the Fc receptor were solubilised from a crude C₃H/He spleen cell membrane fraction. The inhibition of anti-Ia^k induced cytotoxicity measured separately on spleen cells from BALB/c and C₃H/He mice was estimated before and after the Fc receptor had been removed from the other solubilised membrane proteins on an aggregated IgG column. Although more than 80% of the Fc receptor could be eliminated from the bulk of material passing unretarded through the column, the content of Ia antigens was unchanged in this fraction. Furthermore, the isolated Fc receptor did not measurably impede the cytotoxic activity of the anti-Ia^k serum.

Trypsin treatment of spleen cells does not affect the presence of the Fc receptor on B cells³. Accordingly, C₃H/He spleen cells were digested with trypsin as described³ and the amounts of Fc receptor and Ia antigens reacting with the appropriate antisera on the cell surface were quantitatively estimated before and after the proteolytic digestion. Whereas trypsin treatment did not change significantly the amount of antibodies bound to the Fc receptor, more than 80% of the Ia antigens were lost. Thus, our results fail to demonstrate a physical association between the Fc receptor and the Ia antigens.

In conclusion, murine B cells seem to carry a glycoprotein which binds to antigen-antibody complexes. Antiserum against this macromolecule abolishes the binding of aggregated IgG to B lymphocytes, demonstrating that the isolated polypeptide chain constitutes the whole or part of the Fc receptor. Although antibodies against Ia also impede the binding of aggregated IgG to B cells, several attempts to demonstrate the presence of

Ia antigenic determinants on the Fc receptor were unsuccessful. This information, together with the fact that the molecular weight of the Ia antigens is only about half that of the isolated Fc receptor¹⁰⁻¹³, suggests that the Fc receptor is distinct from the Ia antigens. The effect of antisera against Ia antigens to displace aggregated IgG does not seem to depend on a physical linkage between these antigens and the Fc receptor but may merely reflect a situation where the Fc receptor in the cell membrane is located adjacent to the Ia antigens.

Table 3 Relationship between Ia antigens and the Fc receptor on the cell surface

Antibody specificity*	Target cells	Pretreatment of cells	Dead cells (%)
18-15,000	H-2 ^k	NRS	47 ± 4
18-15,000	H-2 ^s	NRS	44 ± 3
Ia ^k	H-2 ^k	NRS	55 ± 9
Ia ^k	H-2 ^s	NRS	6 ± 3
Ia ^s	H-2 ^k	NRS	4 ± 2
Ia ^s	H-2 ^s	NRS	41 ± 6
18-15,000	H-2 ^k	18-15,000	6 ± 4
18-15,000	H-2 ^s	18-15,000	8 ± 3
Ia ^k	H-2 ^k	18-15,000	51 ± 7
Ia ^s	H-2 ^s	18-15,000	44 ± 5

Spleen cells from C₃H/He (H-2^k) or A.SW(H-2^s) mice were suspended in Eagle's MEM with 10% FCS at a final concentration of 20×10^6 cell per ml. Samples of 200 μl were pretreated with 50 μl of antiserum against the Fc receptor or with normal rabbit serum (NRS) for 4 h in a 5% CO₂ atmosphere at 37 °C. After incubation the cells were washed twice in cold Hanks' MEM with 5% FCS. The cell concentration was adjusted to 1×10^6 cells per ml, 25 μl samples were subjected to the cytotoxicity assay with use of the antiserum indicated. Dead cells were stained with Trypan blue. At least 200 cells were examined in each test. The data are the mean ± s.e.m. of three to five experiments.

* The A.TH anti-A.TL (anti-Ia^k) and the A.TL anti-A.TH (anti-Ia^s) antisera were given by Dr G. Hämmerling. All antisera were heat inactivated before use and freed from aggregated IgG by ultracentrifugation.

We thank Dr G. Hämmerling for anti-Ia sera and Ms Y. Fernstedt and Ms E. Harfeldt for technical assistance. This work was supported by grants from the Swedish Cancer Society, Harald and Greta Jeansson Fund, Marcus Borgström Fund and Gustaf V:s 80 års Fund.

Tumour rejection properties of solubilised TSTA from an SV40-induced neoplasm

THE neoplasm mKSA, an SV40-induced sarcoma in BALB/c strain mice has strong, SV40-specific tumour rejection antigens (TSTA). This parental line is also very oncogenic with a tumour dose 50 (TD₅₀) of 10³ cells. A subline, passaged in monolayer tissue culture (mKSA-TC), has a much reduced tumour-inducing capacity (TD₅₀ = 2 × 10⁶–2 × 10⁷ cells). Of these mKSA-TC cells 1 × 10⁵ will immunise syngeneic hosts against a challenge of 1 × 10⁶ mKSA cells carried in an ascitic form (mKSA-ASC); immunisation against other SV40-induced BALB/c sarcomas (for example, SVA31C14 and E4) has also been achieved, but not against Adj-PC-5 (ref. 1) nor against Meth A (ref. 2), both neoplasms carrying specific TSTAs and syngeneic with BALB/c but induced by chemical carcinogens.

Recent work in our laboratory showed that methods developed for isolation and solubilisation of biologically active H-2, histocompatibility antigens^{3,4} could be adapted to obtain soluble immunogenic TSTA from both RNA and DNA virus-transformed neoplasms^{5–7}. Preliminary results were reported of solubilised TSTA with tumour rejecting activity from the non-virus-producing tumour, mKSA, induced by SV40⁸. We now report biological activity of ten consecutive solubilised preparations prepared from membranes of either the mKSA-TC or mKSA-ASC forms of this neoplasm.

The antigen preparations assayed for tumour rejection are designated CM, crude membrane; CS, crude soluble; F-2 and F-3 fractions prepared from Sephadex G-150 chromatography (the included volumes). Tumour cells (2–6 × 10⁶), either from the ascites form or from the cultured subline were collected in Tris-buffered saline, pH 7.4. Cells were washed twice in a solution containing 0.145 M NaCl, 0.005 M Tris-buffer, pH 7.4 and 2 × 10^{–4} M MgSO₄; this solution was adjusted with distilled water to 0.125 M NaCl. The cells were equilibrated in a

cell disruption bomb at 400 pounds inch^{–2} N₂ for 30 min and released rapidly to effect disruption of 90% or more of cells. After removal of nuclei and cell debris the supernatant was centrifuged at 55,000g for 90 min, the new supernatant was discarded and the sediment was suspended in 0.05 M Tris, pH 8.4, at approximately 10 mg dry weight per ml. This CM, was digested with papain at a ratio of 1 mg papain to 100 mg protein, at 37 °C in the presence of 0.01 M dithiothreitol; the reaction was stopped after 1 h by adding iodoacetamide to a final concentration of 0.022 M and insoluble sediment removed by centrifugation at 105,000g for 1.5 h. The soluble supernatant was dialysed exhaustively against 0.15 M NaCl–0.01 M Tris, pH 8.2, and then concentrated by ultrafiltration (Amicon, UM2 membranes). The resulting CS material was applied to Sephadex G-150, the eluate collected and a chromatogram obtained by measuring its absorbance at 280 nm. Fractions F-2 and F-3 were collected and used in the *in vivo* assays. Protein concentrations of CM were determined by dry weight and of CS and the F-2 and F-3 fractions by the method of Lowry *et al.*⁸.

As Table 1 shows, all 10 antigen preparations constituting CM, CS or the chromatographed F-2 and F-3 fractions were effective in immunising BALB/c mice against challenge with the syngeneic mKSA sarcoma. mKSA(TC) and mKSA(ASC) were equally effective and thus share the same TSTA in spite of long-continued passage *in vitro* and *in vivo*. Protection was afforded at cell-challenge concentrations far above the TD₅₀ of 10³ cells. The degree of protection was in the range of that provided by a single subcutaneous injection of 10⁶ or 10⁸ mKSA-TC cells; the immunisation afforded was also rapid and complete. Injections prepared in Freund's complete adjuvant (FCA) were not more immunogenic than those prepared in Tris-buffered saline. A precise dose-response relationship was not observed in those experiments (6a, 6b, 7) in which graded doses of antigen were used for immunisation and graded challenges of mKSA cells were used. This may mean that we were immunising with concentrations of antigen above optimal levels. *In vitro* specific lymphocyte stimulation was also

Table 1 Tumour rejection by membrane antigen preparations of sarcoma mKSA

2a = mKSA CS (preparation 10)	10/15 (25)	50	Meth A 5 × 10 ⁴ cells
2c = none	4/5 (33)	50	Meth A 5 × 10 ⁴ cells

*r², Radius² of subcutaneously growing tumours in mm at 30 d after transplantation.

†CS, papain solubilised membranes; 50 µg injected in CFA × 2, 2 weeks apart. Tumour challenge 2 weeks after last immunisation. Controls received CFA only.

‡These mice were rechallenged after 60 d with 1 × 10⁶ mKSA sarcoma cells and remain negative 45 d after challenge.

observed, using preparations 6b and 7, with concentrations of antigen as low as 0.1 µg per well (0.5 µg ml⁻¹)⁹. This assay presumably reflects a cell mediated immune response.

Our soluble F-2 fraction containing immunogenic material chromatographed as we previously observed with H-2 alloantigens derived from lymphoid cells^{6,7}; nonetheless we also observed our F-3 fraction to be immunogenic. This may represent fragments of the TSTA of low molecular weight produced by excessive papain degradation. Further steps in purification of the mKSA TSTA now in progress, however, should clarify this problem.

In addition to the activity of soluble TSTA from mKSA tumour cells in *in vivo* tumour rejection and in *in vitro* lymphocyte stimulation, specific tumour cell neutralisation was observed using the Winn assay. Sensitised spleen cells from BALB/c mice immunised with several concentrations of the (CS) mKSA could neutralise mKSA tumour cells (Fig. 1). Previous work had shown that the host can recognise TSTA on intact mKSA tumour cells and generate effector cells that specifically destroy the tumour¹⁰.

Specificity of immunogenicity was observed in BALB/c

mice made strongly immune to mKSA antigen and challenged with the syngeneic plasma cell tumour Adj-PC5 (ref. 5). Further demonstrations of specificity are shown in Table 2. Papain-solubilised membranes of BALB/c spleen cells did not confer the capacity to reject mKSA tumour nor did the CS preparation of mKSA sarcoma cells immunise against another BALB/c neoplasm, Meth A, that has its own strong TSTA.

Preliminary comparative studies of the properties of TSTA and H-2 have shown that neither antigen bound significantly to a DEAE-ion exchange column in the presence of 0.05 M NaCl at pH 7.2. In contrast, H-2 bound strongly to a con A affinity column, but TSTA did not (O. H., unpublished). The latter observation suggests that TSTA is a different glycoprotein from H-2, but further purification is required before the antigen can be characterised chemically.

These studies demonstrate that the immunogenic capacity of TSTA like H-2 histocompatibility antigens is preserved by papain digestion and by the limited purification procedures described here. Studies of further purification of SV40-specific TSTA are in progress.

Fig. 1 Results of Winn assay (neutralisation). BALB/c mice were immunised with a single subcutaneous inoculation of preparation 8, CS material in TBS at concentrations of 30 µg (□), 250 µg (○) or 500 µg (●). Two weeks later spleen cells from these immunised groups and from uninoculated controls (Δ) were mixed in a ratio of 100:1 mKSA (ASC) tumour cells and inoculated into BALB/c 8–12-week-old female mice. Sensitised spleen cells from the 250 µg (○) immunised group when mixed with Adj-PC5 (BALB/c) tumour cells and inoculated into syngeneic recipients had no effect on frequency or rate of growth. Data not shown. Differences at 25 d, when 50% of controls had died, in both frequency of progressive growth and mean r² between experimental and control groups were significant ($P < 0.01$).

Possible role for H-Y antigen in the primary determination of sex

In mammals, the genetic basis of sex determination and differentiation seems to be simple^{1,2}. A gene or set of genes on the Y chromosome causes the indifferent embryonic gonad to develop as a testis³. Thus an ovary develops in the absence of the Y and a testis in its presence. The testis then secretes testosterone which induces male development of the accessory glands and ducts^{4,5}. The masculinising action of testosterone on its target cells is mediated by the product of a gene on the X chromosome. This product activates all the genes required for manifestation of the male phenotype in response to circulating testosterone¹. Evidence for this crucial involvement of the

X chromosome in male sexual differentiation comes from a mutation of the relevant gene in the mouse (*Tfm*), resulting in failure to respond to testosterone. A chromosomally XY animal with this mutant gene develops testes, because the Y chromosome is present, but shows no further male differentiation, thus exhibiting the syndrome known as 'testicular feminisation'. This insensitivity to androgen is caused by a mutational deficiency of the nuclear-cytosol androgen-receptor protein not only in mice⁷⁻⁹ but also in man¹⁰. Thus the part that the X chromosome plays in male sexual differentiation has been clarified at the level of an individual gene situated on this chromosome.

The same cannot be said of the part that the Y chromosome plays in inducing testicular development, because no relevant mutation of the presumptive testis-determining gene has been found in any mammalian species, and because we have no clue, therefore, as to the nature of any product specified by this presumptive gene locus. It is clear, however, that the whole Y chromosome is not necessary for this important function. A large part of the mammalian Y chromosome, which as a rule is a relatively minute element, seems to be genetically inert. The observation that an apparent isochromosome of the long arm of the human Y chromosome has no testis-determining function¹¹, indicates that the presumptive testis-determining gene or small cluster of genes resides either on the short arm or on a pericentric region of the acrocentric human Y chromosome.

It is not likely that this presumptive testis-determining gene or set of genes specifies an enzyme or enzymes involved in sex steroid biosynthesis, because the initial biochemical pathways for synthesis of progesterone and oestrogen in the female, and of androgens in the male, are identical. Thus the same enzymes are used by ovary and testis (and to a certain extent by the adrenal) in the production of both male and female sex hormones. Moreover, development of the indifferent gonad into a testis under the influence of the Y chromosome begins as soon as the migration of primordial germ cells from the yolk sac to the gonadal ridge is complete, at which stage endocrine organs in general are not yet fully developed. Thus a cell surface protein or set of proteins concerned in cell-cell recognition and interaction might seem a likely candidate for the gene product or products responsible for initiating testicular differentiation (see below). Under the influence of the Y chromosome, somatic elements of the primitive gonadal ridge differentiate into interstitial cells and Sertoli cells, and as they do so primordial germ cells and Sertoli cells become enclosed within seminiferous tubules, whereas the interstitial cells remain outside. Interaction between the surfaces of somatic elements and germ cells seems essential for the organisation of testicular structure.

By serological methods, those proteins (or the sugar moieties of glycoproteins) which reside in the plasma membrane and are accessible to antibody can be recognised as the surface antigens of intact viable cells. We propose that one such antigen, H-Y (histocompatibility-Y), may be the direct product of the testis-determining gene postulated above.

Rejection of male skin grafts by females within an inbred strain of mice is due to H-Y antigen, found on the cells of all males, but absent from those of normal females (ref. 12; review in ref. 13). Using antibody raised in female mice against cells grafted from males of the same inbred strain, we have found that the cell surface component recognised as H-Y antigen has been highly conserved in vertebrate evolution^{14,15}. Our study of H-Y antigen expression in vertebrates has revealed that H-Y is not in fact specific for males, but rather for the heterogametic sex. Thus in birds and in certain species of Amphibia, female heterogamety of the ZZ/ZW type prevails, and in these animals it is the female whose cells express H-Y antigen¹⁶.

Widespread evolutionary conservation of a particular cell surface component indicates the invariant persistence of a specific function. Our hypothesis is that in the case of H-Y

antigen, this invariant specific function may be to direct the indifferent embryonic gonad to develop towards whichever mature gonad, testis or ovary, typifies the heterogametic sex of each species (testis in XY males and ovary in ZW females).

In mammals the proposed identity of H-Y antigen and the testis-determining gene product can best be tested on exceptional individuals whose gonadal sex does not coincide with their chromosomal sex. In mice and other rodents, a mutational suppression of the Y-linked testis-determining gene should give rise to ovaries in mutant XY individuals, since XO rodents are fertile females¹⁸. According to our hypothesis, such XY individuals would lack H-Y antigen. In man, a similar mutation should give 'streak gonads' in mutant XY subjects, because XO women are sterile¹⁷. Assuming that their streak gonads began as ovaries, these XY women should also type negative for H-Y antigen. On the other hand, a transfer of the testis-determining gene to an autosome, or alternatively, a mutational acquisition of testis-determining function by a dormant autosomal gene, should give rise to testes in mutant XX individuals. These we predict would be typed positive for H-Y antigen. Indeed our preliminary observations indicate that certain XX human males whose cells we have examined express H-Y antigen. Moreover XX mice that are 'sex-reversed' to males by the autosomal dominant, *Sxr* (ref. 18), are also positive for H-Y antigen (D. Bennett, E. A. B., B. M. Cattenach, B. J. Mathieson, M. Scheid, and K. Yanagisawa, unpublished). The original breeding data and cytological observations indicate that if *Sxr* represents a piece of the Y translocated to an autosome, then that piece is so small as to be undetectable karyotypically¹⁸. Therefore the fact that *Sxr*+/+ males express H-Y antigen clearly shows either that the testis-determining gene and the H-Y locus are extremely closely linked, or that the two are in fact one and the same.

Expression of H-Y (male) antigen in phenotypically female *Tfm*/Y mice

THE X-linked testicular feminisation mutant (*Tfm*) in the mouse produces chromosomally male animals, *X^{Tfm}/Y*, with small testes but no other internal reproductive organs, and with female external genitalia¹. This condition results from

failure of target tissues to respond to testosterone, so that all characters of maleness that are testosterone-dependent are absent in males²⁻⁴.

In addition to the development of testes, there is one other attribute of maleness in the mouse which seems not to require testosterone; this is the expression of H-Y antigen, a cell surface component found on all cells of male mice, but on no cells of females⁵. Although some data are controversial, and while quantitative effects of testosterone can be envisaged, the bulk of evidence suggests that H-Y is expressed whenever the Y chromosome is present, and not otherwise.

Among the supporting evidence is the following: (1) Expression of H-Y antigen is not affected by the single-X compared with the two-X constitution; that is, XXY male mice have H-Y antigen whereas XO females do not⁶. (2) Testicular teratomas are H-Y⁺ when they have the Y chromosome but not when Y is lost as a consequence of aneuploidy that may occur on passage⁷. (3) Genetic data coupled with skin-grafting experiments suggest not only that H-Y is, determined by the Y chromosome, but that it may exist in different allelic forms in males of different strains⁸, this is, incidentally the best indication so far that the H-Y-determining gene of the Y chromosome is 'structural' rather than 'regulatory'. (4) Male haemopoietic cells colonising lethally irradiated females continue to express H-Y (ref. 9). (5) In spite of the evidence that neonatal castration may reduce the immunogenicity of male skin grafts¹⁰, deprivation of testosterone has not been shown to eliminate H-Y antigen qualitatively; nor did the administration of testosterone induce H-Y in females¹¹. (6) Evidence that newborn female skin that has been resident on males is rejected on regrafting to females, implying acquisition of H-Y in the male environment, is both claimed¹² and disputed¹³. (7) The heterogametic sex, whether male or female, is H-Y⁺ in other vertebrate species¹³; in fact we must now recognise that the term 'male antigen' is a misnomer in reference to H-Y.

The most likely explanation for all these findings is that H-Y is controlled by a gene or genes on the Y chromosome, and that neither testosterone *per se* nor the male environment is required to elicit activity of this gene or genes.

The evidence is that all testosterone-dependent characters are lacking in *Tfm/Y* animals and that even the *Tfm/Y* embryo is unresponsive to testosterone⁴. Therefore the finding that we report here, namely that *Tfm/Y* mice are H-Y⁺, is strong evidence that the expression of H-Y is testosterone independent.

Mice from the Harwell *Tfm* stock are maintained by crossing *Tfm*+/+/+ *Blot*+/+ *Ta*+/+ *Y* and *Tfm*+/+/+ *Ta*+/+ to + + *Blot*/Y in alternate generations. For the tests described below, the *Tfm* animals were *Tfm/Y* from this stock, the control females were their *Tfm* + + / + *Ta* + siblings, and the control males were + + *Blot*/Y siblings.

Anti-H-Y sera were prepared in C57Bl/6 (abbr B6) females by repeated grafting of B6 male skin. The anti-H-Y activity of such sera is demonstrable by the complement-dependent cytotoxicity assay on sperm¹⁴ or dissociated epidermal cells¹⁵. We used 3 types of experiment: (1) The cytotoxicity assay with anti-H-Y serum on epidermal cells from *Tfm/Y* mice (Fig. 1).

Fig. 1 Demonstration of H-Y antigen on dissociated epidermal cells of *Tfm/Y* mice by the complement-dependent cytotoxicity assay test with anti-H-Y serum. The data in this figure are from a representative test with two mice of each genotype. The values shown are mean readings for the pairs of mice. The anti-H-Y serum was preabsorbed twice with female epidermal cells (4 parts serum undiluted: 1 part packed cells) at 0-4 °C. Complement source was selected rabbit serum, absorbed with thymocytes, lymphocytes, and epidermal cells in the presence of EDTA (see ref. 15), diluted 1/6 before use. Percentage dead epidermal cells (ordinate) calculated by the formula $\{(a-b)/(100-b)\} \times 100$ where *a* is the % dead cell count (Trypan blue stained cells) after incubation with antibody and complement; and *b* is the similar count with antiserum omitted. This somewhat lower reaction of *Tfm/Y* epidermal cells, compared with control male cells is not significant, and was not a feature of other similar tests. Δ, *Tfm/Y*; ●, + + *Blot/Y* (normal male control); ○, *Tfm* + + / + *Ta* + (normal female control).

(2) Absorption of anti-H-Y serum with spleen cells from *Tfm/Y* mice followed by testing for cytotoxicity on sperm (Fig. 2). (3) Grafting of *Tfm/Y* skin to B6 females to determine whether this would presensitise them for a second-set response to subsequent grafting of B6 male skin (Table 1). Figure 1 gives one representative example out of a total of five positive cytotoxicity tests with anti-H-Y serum on *Tfm/Y* epidermal cells. Figure 2 shows two positive absorption tests with *Tfm/Y* spleen cells. Table 1 summarises the results of the grafting experiments, in which *Tfm/Y* skin grafts sensitised B6 females to subsequent B6 male skin grafts. In all of these tests, cells from *Tfm/Y* mice have proved indistinguishable from those of normal males in their expression of H-Y.

We conclude that H-Y is not testosterone dependent. Since the *Tfm/Y* animals have small testes, which seem fairly normal at foetal to neonatal stages⁴, one must consider whether it is the presence of testes which determines the production of H-Y antigen or whether the presence of the Y chromosome itself is sufficient. The concept that some influence of a gonad could affect surface antigenicity of cells of other tissues, seems very difficult to accommodate within existing knowledge. Furthermore, it is not yet certain when Y-antigen expression begins during development, and so it may in fact precede

Table 1 Second-set rejection of B6 male skin by B6 females previously grafted with *Tfm/Y* skin*

First graft (number of B6 females grafted)	Rejection time (d) of B6 male skin grafted 2-3 months later	MST† (confidence limits)
<i>Tfm/Y</i> (15)	11, 12, 13, 13, 13, 14, 14, 14, 15, 15, 16, 16, 17, 17.	14 (12.7-15.4)
+ + <i>Blot/Y</i> ; male controls (13)	12, 12, 15, 15, 16, 16, 16, 17, 17, 18, 18, 22, 22.	15.5 (13.5-17.8)

Fig. 2 Demonstration of H-Y antigen on *Tfm/Y* spleen cells by absorption of cytotoxic activity from anti-H-Y serum. The data shown illustrate a representative test. Each point represents the mean value obtained when spleen cells from two different mice of the same genotype were tested separately. The anti H-Y serum (preabsorbed with female epidermal cells, see footnote to Fig. 1) was diluted 1/4 and absorbed in 0.1-ml volumes with spleen cells from *Tfm/Y* mice or control mice as indicated, for 30 min at 0–4 °C; after centrifugation to remove the cells, the absorbed serum was titrated against sperm for residual cytotoxic activity, using horse serum diluted 1/8 as the complement source. The tests were read 'blind' with absorbed antiserum sample coded. Percentage sperm dead (ordinate) was calculated by the formula $\{(a-b)-(100-b)\} \times 100$, where a is number of sperm dead, and b is the % dead sperm in original suspension (method described in detail elsewhere¹⁴). Sperm were obtained from unrelated normal mice. H-Y antiserum absorbed with: △, *Tfm/Y*; ●, + + *Blo/Y* (normal male controls); ○, *Tfm* + + + *Ta*+ (normal female controls).

testis formation. We prefer to consider that the detection of H-Y in these *Tfm/Y* phenotypic females with a Y chromosome constitutes further compelling evidence that H-Y is indeed Y dependent, not male dependent.

Effect of morphine on a depolarising dopamine response

THE structural complexity of nervous tissues and the presence of non-neuronal elements have hindered investigations into the actions of morphine at the cellular level in the vertebrate central nervous system, and contribute to the difficulty of determining whether morphine acts pre- or postsynaptically. Although presynaptic effects of morphine are documented, to our knowledge there has been no demonstration of an effect

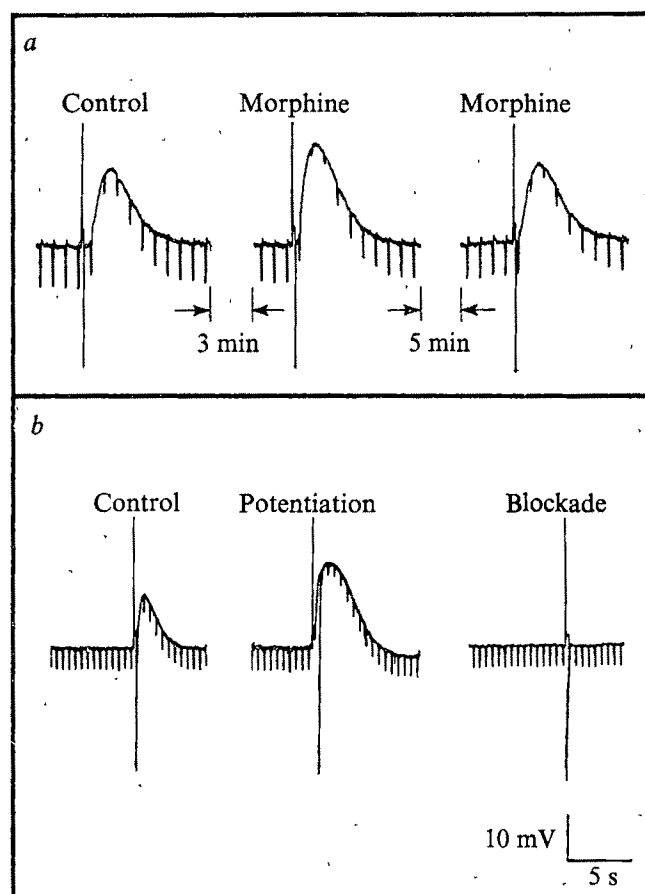

Fig. 1 *a*, Potentiation of the DA response by low morphine concentrations. DA iontophoretic charge, 500 nC. Current pulse amplitude was maintained constant at 0.26 nA for the duration of the experiment. *b*, Potentiation of the DA response by low morphine concentrations followed by blockade of the response at higher morphine concentrations in the same cell. Morphine added to the bath (0.5 μM) caused an increase in the DA response amplitude. An excess of morphine (24 μM) blocked the DA response. Potentiation could be attained with 0.2–0.6 μM morphine and blockade with 8–12 μM morphine. DA iontophoretic charge, 300 nC. Current pulse amplitude was maintained constant at 0.15 nA for the duration of the experiment. Morphine in the concentration range tested (0.1–50 μM) had no effect on the passive membrane properties. Polarising current pulses were passed across the membrane to determine conductance changes. Standard electrophysiological techniques using a bridge circuit recorded membrane potential and passed polarising current intracellularly simultaneously. Glass microelectrodes filled with either potassium acetate or chloride and with resistances greater than 30 MΩ were used for recording. During recording, the 35-mm Falcon culture dish on which the cells were grown remained covered except for a 1-cm hole in the centre to allow for entry of electrodes. The culture dish was maintained at 37 °C and gassed continually with a stream of water-saturated 10%–95% carbon dioxide–air mixture. There was negligible evaporation of growth medium during any one recording session. 3,4-Dihydroxyphenylethylamine (dopamine)-HCl (Sigma) was prepared in aqueous 1 M concentrations (pH 3–4) and used to fill iontophoretic glass microelectrodes, the final resistance of which was adjusted to 10–20 MΩ by bumping the electrode tip.

of morphine on postsynaptic neurotransmitter receptors using intracellular recording techniques.

We have studied the effects of morphine on the dopamine response of the somatic cell hybrid 108CC-15. The cell line is a product of the fusion of cells from the mouse neuroblastoma N18TG2 and the rat glioma C6-BU-1 and expresses a number of neuronal phenotypes¹⁻⁴. It is a homogeneous population of cells, allowing intracellular recording from single cells free of organisational complexity or synaptic input. The biochemical and electrical properties of the cell line have been described in detail elsewhere¹.

When dopamine (DA) is applied iontophoretically, a depolarising response, mediated by a conductance increase, is seen in 64% of the cells. The average resting membrane potential was -42.5 mV with an average input resistance of 39 m Ω . The DA response has a reversal potential of -15.9 mV (± 1.2). Repeated application of DA at close time intervals resulted in desensitisation of the response. The response is blocked by the catecholamine antagonists bulbocapnine, chlorpromazine, and phentolamine; the dopamine metabolite 3-methoxytyramine, and the acetylcholine antagonists hexamethonium and α -bungarotoxin, are without effect. Details of cell growth for this electrophysiological study and additional characteristics of the DA response are published elsewhere²².

Fresh solutions of morphine sulphate (Mallinckrodt) and naloxone HCl (Endo Laboratories) were prepared before each

experiment. After each drug application to the bath, adequate time was allowed (5–10 min) to allow equilibration of the drug in the medium. Morphine was applied iontophoretically from glass micropipettes filled with 1% morphine sulphate. Morphine (0.1 – 50 μ M) and naloxone (1 – 10 μ M) had no effect on the passive membrane properties. Current pulses were injected continuously during drug applications and demonstrated that there were no changes in membrane resistance or membrane potential.

Morphine at low bath concentrations (0.2 – 0.6 μ M) increased the DA response amplitude up to 75% above control levels (Fig. 1a). The increase was transient, since the response amplitude was observed to return to control levels and in most cases, it was not possible to repeat the potentiation on the same cell after the initial exposure to a low morphine concentration. The potentiation was also observed with iontophoretic application of morphine.

Higher bath concentrations of morphine (8 – 12 μ M) blocked the DA response and it remained blocked as long as morphine was present in the bath. Figure 1b shows potentiation of the DA response in a single cell at low concentrations but that on addition of more morphine to the bath, the DA response was blocked. Iontophoretic application of morphine blocked the DA response and this block was dose dependent and reversible after diffusion of the drug into the medium (Fig. 2a). When morphine was added to the bath in sufficient concentration to block the DA response, addition of equimolar naloxone reversed the blockade and the DA response recovered to control levels (Fig. 2b). This observation agrees well with the known antagonist action of naloxone on morphine.

In both peripheral and central nervous tissues, various lines of evidence have suggested both a pre- and postsynaptic effect of morphine. A presynaptic action of morphine is argued from studies of the uptake, metabolism and release of neurotransmitters⁵⁻¹³. Inferences on the postsynaptic action of morphine are based on morphine interaction with neurotransmitter antagonists¹⁴⁻¹⁷. In a separate study, Bradley and Dray¹⁸ found both potentiation and inhibition of neurones when morphine was applied iontophoretically to brain stem. The potentiation was observed to "desensitise". Our results support the view that morphine acts at least postsynaptically. Pert and Snyder¹⁹ first demonstrated that opiate receptors exist in the brain; Klee and Nirenberg²⁰ have demonstrated that 108CC-15 has opiate receptors with characteristics similar to brain receptors. That morphine influences the DA response suggests the existence of some relationship between opiate receptor binding and neurotransmitter receptors. Although Pert and Snyder²¹ have shown that catecholamines do not block binding of morphine to its receptor, their results do not preclude a specific interaction of morphine with the DA receptor.

We thank Dr Berndt Hamprecht on whose cell line this work was done and Drs David Carpenter and James Blosser for their discussions and criticisms.

Fig. 2 a, Dose-response characteristic of the morphine blockade. Morphine applied iontophoretically in increasing quantities decreased the DA response amplitude in a dose-dependent fashion. The blockade was reversible after diffusion of the drug into the medium and the blockade could be repeated on the same cell. In recordings b, c, and d the first stimulus artefact represents morphine application and the second represents DA application. The time between drug applications was 2 min. a, 300 nC DA; b, 50 nC morphine, 300 nC DA; c, 100 nC morphine, 300 nC DA; d, 200 nC morphine, 300 nC DA; e, 300 nC DA. Current pulse amplitude was maintained constant at 0.5 nA for the duration of the experiment. b, Reversal of the morphine block by naloxone. After sufficient morphine was added to the bath to block the DA response (7.3 μ M), an equimolar amount of naloxone was added and the DA response returned to control levels. DA iontophoretic charge, 300 nC. Current pulse amplitude was maintained constant at 0.3 nA for the duration of the experiment. Naloxone added to the bath alone had no effect on the membrane passive properties nor the DA response. In similar experiments, longer time periods were allowed after the addition of morphine to the bath to ensure equilibration and that return of the DA response after addition of naloxone to the bath was not purely coincidental.

Receptor potential and impulse initiation in two varieties of reptilian muscle spindle

AMONG muscle spindles, those in snake and lizard are the simplest in structure, consisting of a single intrafusal muscle fibre innervated by a single sensory and several motor nerve fibres. Two varieties of spindle occur: one type, the long-capsule spindle has a longer and more slender capsule than the other, the short-capsule spindle¹. They differ in their responses to stretch; the response of the long-capsule spindle depends mainly on degree of stretch while the short-capsule spindle responds both to velocity and amplitude of stretch^{2–4}.

Sensory transduction in muscle spindles involves the following steps: transmission of mechanical stimulus (stretch) through intrafusal fibres, generation of receptor potential in the sensory terminals and impulse initiation in the afferent fibre. While there is information on the mechanical transmission in reptilian spindles⁵ and on the characteristics of the impulse initiating process⁶, there has been no study of the receptor potential in long- and short-capsule reptilian spindles in response to stretch. We report here some features of receptor potential characteristic of each type of snake spindle which may account for differences in the early adaptation of impulse discharge between the two types of spindle.

Muscle spindles in ventral costocutaneous muscles of garter snake (*Thamnophis*) were used. The technique for dissection of the muscle and the ionic composition of the bathing solution have been described elsewhere⁷. After visual identification of the type of spindle under the dissecting microscope and dark field illumination, a single spindle was isolated with some extrafusal fibres which served as a support. Each end of the muscle was tied to a nylon rod which was connected to one of a pair of Brush pen motors. The muscle spindle was stretched to both sides by a computer (LINK) controlled activation of Brush pen motors at a rate of once every 5 s. The isolated spindle was brought near the interface between snake Ringer's solution and liquid paraffin and the nerve was lifted into liquid paraffin on one of a pair of glass pipettes filled with agar-Ringer. The other pipette was placed in the Ringer's solution. Each pipette was connected to one of a pair of half calomel cells and signals from the nerve were amplified by a PAR amplifier. Most of the experiments were done at the muscle length at which slack was just taken up. Tetrodotoxin (TTX) of 10⁻⁷–10⁻⁸% was used to block impulse initiation in the ending. After each experiment the nerve was crushed with a pair of fine forceps at the region close to the capsule. In all cases examined no noticeable movement artefact was observed. Experiments were performed at room temperature (about 25 °C).

Figures 1 and 2 illustrate examples of responses of a short-capsule and a long-capsule spindle, respectively, to ramp-and-hold stretch of increasing velocity (from a to d) before (left column) and after (right column) application of TTX. Several components may be recognised in the dynamic component of the receptor potential particularly in short-capsule spindles. At the beginning of stretch there is a steep rise of receptor potential (initial component) and at the end of the ramp the potential swings back to a lower level (dynamic-static fall)

often making an undershoot (dynamic-static undershoot). Between the initial component and the dynamic-static fall the potential shows either a plateau or gradual decay or increase depending upon the type of spindle and the velocity and amplitude of stretch. During the hold phase of stretch the potential gradually declines (adaptive static fall) and at the end of stretch the potential may show "release undershoot" before returning to the original level (the above terminology adopted from ref. 8). In the long-capsule spindle the initial component and the dynamic-static undershoot are both usually lacking. The initial component may correspond to the initial burst of discharge which often occurs in short-capsule, quite rarely in long-capsule spindles. The dynamic-static undershoot may correspond to the pause of impulse activity which occurs just after the ramp as may be seen in Fig. 1. The above features of receptor potentials characteristic of the short-capsule and the long-capsule spindles are strikingly similar to those recorded from the primary and the secondary endings, respectively, in cat muscle spindles⁸. In order to examine the relation between dynamic components of receptor potential and impulse discharge the threshold depolarisation of receptor potential (zero frequency on ordinate) for initiating a train of impulses was determined by extrapolating the approximately linear relation between mean static frequency and receptor potential 0.5 s after the ramp phase of stretch of varying amplitude. The scaling of frequency on the ordinate was then adjusted so that the mean static frequency and the receptor potential 0.5 s after the ramp coincide each other. The results thus obtained are shown in Figs 1 and 2 as filled triangles superimposed on each receptor potential. In both types of spindle when the velocity of stretch is slow the frequency of impulse discharge follows relatively well the dynamic component of receptor potential. As the velocity of stretch increases the discrepancy between the two parameters increases progressively. Particularly in short-capsule spindles the dynamic impulse frequency rises far above the level of receptor potential.

The progressive discrepancy between discharge frequency and the receptor potential with the increase in velocity of stretch could be accounted for by accommodative process occurring

Fig. 1 Responses of a short-capsule spindle to ramp-and-hold stretch of increasing velocity (from a to d, see each lower trace) before (left column) and after (right column) application of 10⁻⁸ TTX. Records were all reproduced from tape. A pair of records in a single row are responses to an identical stretch. Velocity of stretch (mm s⁻¹); a, 1.0; b, 5.0; c, 10.0; d, 15.0. Amplitude of stretch, 500 µm. Arrows indicate threshold level of receptor potential for the first spike. Triangles, frequency of impulse discharge before application of TTX (explanation of scaling in text). Ordinate, impulses s⁻¹. Time calibration, 0.5 s. Voltage calibration (250 µV) applies to all records of response.

Fig. 2 Responses of a long-capsule spindle to ramp-and-hold stretch of increasing velocity (from *a* to *d*) before (left column) and after (right column) application of 10^{-6} TTX. Records are arranged in the same way as in Fig. 1. Velocity of stretch (mm s^{-1}); *a*, 1.0; *b*, 5.0; *c*, 10.0; *d*, 15.0. Amplitude of stretch, 350 μm . Arrows and triangles, threshold depolarisation for the first spike and impulse frequency plotted as in Fig. 1 respectively. Ordinate, impulses s^{-1} . Time calibration, 0.5 s. Voltage calibration (200 μV) applies to all records of response.

in the spike initiating site. In fact, with decrease in stretch velocity substantial increase in the threshold depolarisation for the first spike may be seen in Figs 1 and 2 (arrows). On the basis of accommodation it may be predicted that the larger the dynamic component of receptor potential the larger the discrepancy would occur between impulse frequency and receptor potential as illustrated in Figs 1 and 2. Another possibility for the discrepancy may be the preferential suppression of the dynamic component of receptor potential by TTX. This seems less probable because (1) after application of TTX the dynamic discharge is always the last to be blocked, (2) higher concentration of TTX (10^{-5}) does not seem to affect appreciably the receptor potential and (3) as in Figs 1 and 2 the dynamic impulse frequency and the dynamic receptor potential at low velocity of stretch coincide rather well with each other. Whatever the underlying mechanism is, however, it may be concluded that the basis for the difference in stretch-velocity sensitivity between the two types of spindle is due mainly to the difference in the dynamic component of the receptor potential. Taking the previous findings^{5,6} into consideration it follows that either the mechanical event occurring at the ultrastructural level particularly in the sensory ending-intrafusal fibre contact region and/or in the ionic mechanisms for generating receptor potentials in the sensory ending may be responsible for the stretch-velocity sensitivity of snake muscle spindles.

I thank Professor C. C. Hunt for suggestions on the manuscript.

Binding of aldosterone by mitochondria-rich cells of the toad urinary bladder

ALDOSTERONE causes a large increase in the active transport of sodium by the urinary bladder¹ of the toad. This response, analogous to the effects of the steroid on the kidney, has been the object of considerable biochemical study². Aldosterone also enhances the stimulation by neurohypophyseal hormones of sodium and hydro-osmotic flux^{3,4}. Because the response in sodium transport seems quantitatively related to the increment of cyclic AMP generated by vasopressin⁵, augmentation of the sodium response is presumably related to the larger increment of intracellular nucleotide induced by a given dose of vasopressin in steroid-treated bladders⁶. Using a technique for separating the two major cell types of the bladder mucosal epithelium—the granular (G) and the mitochondria-rich (MR) cells—we found that a response to neurohypophyseal hormones, as reflected by hormone-induced increases in the intracellular cyclic AMP content, is apparently limited to the MR cell⁷. This apparent synergism of the neurohypophyseal and steroid hormones on transport suggests that their loci of action are in close proximity. We therefore examined the binding of ³H-aldosterone by the two major cell types.

To measure the specific binding of ³H-aldosterone by mineralocorticoid receptors, we incubated paired sets of 6–10 intact hemibladders in separate baths. One bath (³H-aldo) contained ³H-aldosterone alone in various concentrations, while the paired bath (control) contained the same concentrations of ³H-aldosterone plus a 1,000-fold excess of unlabelled steroid. After incubation for 90 min, the mucosal cells were removed by immersing the bladders in EDTA–Ringer solution. The MR and G cells of each set of bladders were separated by density gradient centrifugation⁷ and the ammonium-sulphate precipitable ³H-aldosterone was measured in each of the four preparations. The difference in the ³H-aldo and control values for each cell type was assumed to represent specifically-bound or displaceable steroid (Table 1).

We found that the amount of displaceable ³H-aldosterone in MR cell preparations was related directly to the concentration of labelled steroid in the bath. With the exception of a single experiment, there was no significant binding of displaceable aldosterone by G-cell preparations. We also measured the specific binding of corticosterone, the natural glucocorticoid of *Bufo marinus*, by the two cell types. ³H-corticosterone (New England Nuclear, 84 Ci mmol⁻¹), 10^{-8} M, and a 1,000-fold excess of unlabelled corticosterone, were used as in the aldosterone binding studies. The amount of displaceable corticosterone bound by the G cells (2.6×10^{-14} mol per mg protein) was equivalent to that bound by the MR cells (2.95).

The displaceable aldosterone bound by the MR cells was considerably greater in April than values measured during September to March. This increased level of binding persisted until late August when successive experiments at the level of 5×10^{-9} M ³H-aldosterone showed a progressive decrease in the amount of steroid bound by the MR cell (from the expected 28.0) to 9.5, 8.9, 2.9 and 2.1×10^{-14} mol ³H-aldosterone per mg protein. This compared with a value of 2.15 obtained the previous March (Table 1). This marked variability in the amount of aldosterone bound by the MR cells corresponds and may be related to the well known seasonal variations in the responsiveness of the toad bladder transport mechanisms to mineralocorticoid hormones.

The mineralocorticoid/glucocorticoid selectivity of the receptor binding aldosterone was examined by measuring the efficacy with which deoxycorticosterone (DOCA) and cortisol displaced ³H-aldosterone. Hemibladders were incubated in three sets. In addition to ³H-aldo and control sets used in previous experiments, the third set was exposed to either DOCA or cortisol in 200-fold excess as well as ³H-aldosterone.

Table 1 Specifically bound ^3H -aldosterone in separated mitochondria-rich and granular cells

	^3H -aldosterone ($\text{M} \times 10^{-9}$)	Mitochondria-rich cells			Granular cells		
		^3H -aldo	Control	Net	^3H -aldo	Control	Net
November–March	1.2	1.38	0.84	0.54	0.73	0.74	0

	40.0	88.00	1.80	86.2	1.77	1.91	0

Toads (*B. marinus*) of Colombian origin (Tarpon Springs Inc.) were kept in 0.6% saline for at least 3 d to suppress endogenous aldosterone. Cells were derived from two sets of 8–12 urinary hemibladders incubated for 90 min in Ringer containing NaCl, 85 mM; KCl, 4 mM; NaHCO_3 , 17.5 mM; KH_2PO_4 , 0.8 mM; MgSO_4 , 0.8 mM; CaCl_2 , 1.5 mM; dextrose, 10 mM; and ^3H -aldosterone (New England Nuclear, 91.6 Ci mmol $^{-1}$), in the indicated concentrations. The control bath also contained a 1,000-fold excess of unlabelled aldosterone. The mucosal cells were removed by incubation in EDTA–Ringer and the MR and G cells separated by centrifugation on a discontinuous density gradient of Ficoll⁷. The MR and G cells from the ^3H -aldo and control tissues were sonicated and the radioactivity measured in the ammonium sulphate (50% saturated) precipitable fraction of the 110,000g supernatant. The specifically bound steroid in each experiment, the difference between the ^3H -aldo and control, is expressed as mol $\times 10^{-14}$ per mg protein.

As Table 2 shows, DOCA, a potent mineralocorticoid, completely displaced ^3H -aldosterone from the MR cells. Cortisol, primarily a glucocorticoid, displaced only about 24% of the specifically-bound aldosterone, indicating high mineralocorticoid specificity for the ^3H -aldosterone binding sites.

The subcellular distribution of displaceable ^3H -aldosterone was determined in unseparated mucosal cells. Intact hemibladders were incubated as 10 paired sets of ^3H -aldo and control tissues. Both bathing solutions contained 10^{-8} M ^3H -aldosterone and the control bath also contained 10^{-5} M unlabelled aldosterone. After incubation for 90 min the mucosal cells were removed and the two suspensions of mucosal cells were disrupted by pressure homogenisation, which leaves the nuclei intact. The homogenates were fractionated by differential centrifugation and ammonium sulphate precipitation. In bladders incubated in ^3H -aldosterone alone, 1,222 c.p.m. representing approximately 12% of the steroid in the homogenate, sedimented with the nuclei (Table 3). Receptor-dependent uptake of aldosterone by the nucleus is demonstrated by the large reduction in the amount of labelled steroid sedimenting with the nuclei prepared from control tissues (4.6%). The ^3H -aldosterone bound by the ammonium sulphate precipitate prepared from the supernatant fraction of the cell also demonstrated significant displacement by unlabelled steroid. These data, which confirm earlier studies⁸ of subcellular localisation of aldosterone, indicate that the steroid is bound by specific receptors in both the nucleus and the cytoplasm of the mucosal cell.

The identification of the MR cell as the aldosterone-binding locus in the bladder mucosal epithelium is reinforced when

displaceable steroid is determined in the nuclei from isolated MR cells. Using incubation procedures described earlier, the MR cell nuclei from ^3H -aldo (10^{-8} M) and control tissues were isolated. The nuclei from the ^3H -aldo set contained 7,650 c.p.m., which when compared with only 60 c.p.m. in the control nuclei, indicates nuclear accumulation of aldosterone by a specific receptor mechanism in the MR cells.

Our data demonstrate the specific, concentration-dependent binding of aldosterone by the MR cells and localisation of the steroid within the nucleus. These results, together with our demonstration that aldosterone induces the synthesis of protein in MR cells¹⁰, imply a transcriptional effect of aldosterone.

Table 3 Subcellular distribution of ^3H -aldosterone in isolated mucosal cells

Subcellular fraction	^3H -aldo	Control
Nucleus	12.0%	4.6%
Postnuclear pellet	10.6	11.8
Supernatant	84.1	87.5
$-(\text{NH}_4)_2\text{SO}_4$ precipitate	8.4	5.1

Paired sets of hemibladders were incubated as in Table 1; the concentration of ^3H -aldosterone was 10^{-8} M. After 1.5 h mucosal cells were removed by incubation in Ringer containing EDTA (2 mM) with no Ca^{2+} or aldosterone present. Mucosal cells were disrupted by pressure homogenisation; the samples were equilibrated for 30 min with nitrogen at 1,350 pounds inch $^{-2}$ before release⁹. Nuclei were sedimented by centrifugation at 600g for 20 min. The 600g supernatant was centrifuged at 110,000g for 30 min (postnuclear pellet) and protein in this supernatant precipitated by ammonium sulphate (50% saturated). Radioactivity was measured by liquid scintillation and the radioactivity in each fraction expressed as the percentage of that in the original homogenate.

Table 2 Effects of DOCA and cortisol on aldosterone binding in toad bladder MR cells

Date	^3H -aldo	Control	Competing steroid DOCA	Cortisol	%Displacement of ^3H -aldo by competitor
8/28	15.7	6.2	5	—	> 100
8/30	14.7	5.8	—	12.3	27
9/10	7.4	4.5	—	6.8	21
9/18	3.6	1.4	1.2	—	> 100

Three sets of eight hemibladders were used: ^3H -aldo, hemibladders incubated in 5×10^{-8} M ^3H -aldosterone; control, hemibladders incubated in 5×10^{-8} M ^3H -aldosterone plus 5×10^{-6} M unlabelled aldosterone; and either DOCA or cortisol, hemibladders incubated in 5×10^{-8} M ^3H -aldosterone plus the competing steroid (10^{-6} M). The values given (in mol $\times 10^{-14}$ ^3H -aldosterone per mg ammonium sulphate-precipitable protein) are the amounts of ^3H -aldosterone bound by the MR cells in each set of hemibladders.

These observations, together with earlier evidence that the MR cell is the target of neurohypophyseal hormones⁷, indicate that the MR cell is the initial locus of action of natriuretic hormones. Other investigators have suggested that the MR cell is the site of action of aldosterone¹¹. Although the G cells may well participate in the hormone-induced sodium and hydro-osmotic fluxes¹², our data indicate a unique role for the MR cells in the hormonal regulation of transport in this tissue. Indeed, the unique stellate arrangement of G cells around the less numerous MR cells¹³ raises the possibility that the two cell types may act cooperatively in the tissue's response to peptide and steroid hormones.

Cytochalasin B increases collagenase production by cells *in vitro*

COLLAGENASE is one of the major enzymes involved in the remodelling of connective tissues in normal and pathological states. Specific collagenases have been isolated from the culture media of many tissues *in vitro*¹ and have been found in culture media from various cells in monolayer culture, including rabbit synovial fibroblasts², guinea pig macrophages^{3,4} and human skin fibroblasts⁵. For a better understanding of the mechanisms by which collagenases are synthesised and released from cells, studies have focused on agents that stimulate these processes. Endotoxin⁶ and lymphokines⁴ induce release of collagenase from guinea pig macrophages, and a sustained release of collagenase and neutral protease from rabbit synovial fibroblasts was produced by phagocytosis of polystyrene latex particles⁷. It seems likely that all these agents affect cell membrane function, and so we have tested the effect on collagenase production by rabbit synovial fibroblasts of cytochalasin B (CB), which perturbs membranes in ways similar to phagocytosis⁷.

Fibroblast-like cells grown out from primary explants of rabbit synovium were dissociated mechanically or by a trypsin-EDTA mixture and then grown to confluence in glass prescription bottles in Dulbecco's modified Eagle's medium (DMEM) fortified with 10% foetal calf serum (FCS). Cells from the sixth to fourteenth passage generations were used. Human cells derived from synovial membrane were obtained in similar fashion from tissue provided by Mr Alan Murley, Orthopaedic Section, Addenbrooke's Hospital, Cambridge. Human skin fibroblasts grown from two normal children and from a child with the Hurler syndrome (type I mucopolysaccharide storage disease) were the gift of Dr William Sly, Department of Paediatrics, Washington University, St Louis, Missouri.

For studies with CB, cells were passaged into Nunclon plastic cell culture dishes (diameter 25 mm) and used when they approached confluence. As Figure 1 shows there was a large increase in collagenase activity in culture medium from CB-treated rabbit cells ($1 \mu\text{g ml}^{-1}$). CB caused cells to retract cytoplasm around nuclei, leaving thin cell processes extending in multiple directions, and this effect was greater in cells exposed to $10 \mu\text{g ml}^{-1}$; at $0.1 \mu\text{g ml}^{-1}$, CB caused

Fig. 1 Stimulation by CB of collagenase in cultures of rabbit synovial fibroblasts. CB was made up in a stock solution in DMSO (5 mg ml^{-1}) and diluted in DMEM before use. DMSO (0.1–1%) had no effect on collagenase production or activity. Medium containing 10% FCS was replaced with serum-free medium at time 0 and subsequently collected every 48 h. Collagenase activity was assayed using ^{14}C -labelled collagen fibrils as substrate (reaction mixture: $100 \mu\text{l}$ 0.2% collagen, $80 \mu\text{l}$ culture medium, $20 \mu\text{l}$ 0.01 M *p*-chloromercuribenzoate and $100 \mu\text{l}$ 0.1 M Tris-HCl, pH 7.6, 0.03 M CaCl_2). Incubation was for 18 h at 37°C . The protein content, determined by the method of Lowry *et al.*¹⁴, of cells adhering to dishes at the end of the experiment did not differ significantly among groups. Duplicate assays were performed on all samples. Values for CB at $10 \mu\text{g ml}^{-1}$ represent two dishes (a). Eight dishes received CB at $1.0 \mu\text{g ml}^{-1}$ (b) and there were four control dishes (c); means \pm s.e.m. are shown for control samples, and those treated with CB at $1.0 \mu\text{g ml}^{-1}$. The cumulative enzyme release from the cells treated with CB at $1.0 \mu\text{g ml}^{-1}$ was different from the controls ($P < 0.01$).

no morphological changes and no increase in collagenase activity. Concentrations of CB $> 10 \mu\text{g ml}^{-1}$ in the absence of FCS were toxic to cells; many became detached from the dishes. It is not essential to preincubate cells with CB in the presence of FCS to stimulate collagenase release, but removal of CB from medium resulted in a prompt fall in collagenase release to control levels.

Studies with the human fibroblasts have given essentially similar results (Table 1). Dissociated cells were added to duplicate dishes in dilutions of zero (2×10^5 cells ml^{-1}), 1:1 (10^5 cells ml^{-1}) and 1:3 (0.5×10^5 cells ml^{-1}). CB ($1.0 \mu\text{g ml}^{-1}$) was then added only to the cells diluted 1:1. More collagenase was released from untreated Hurler cells than from untreated normal cells, as noted by others (unpublished results of Z. W., W. Sly and J. T. Dingle). The fractional increase over control levels of enzyme release induced by CB was, however, greater in the fibroblasts derived from normal skin.

The cumulative collagenase activity released from human fibroblast-like cells (eighth passage) derived from synovium removed during insertion of a prosthetic hip in a 75-yr-old woman with degenerative arthritis was determined, using a protocol similar to that described in the legend of Fig. 1. In the 6 d of culture after addition of serum-free medium containing CB ($1.0 \mu\text{g ml}^{-1}$) there was a cumulative mean collagenase activity (U) in four dishes of $1,423 \pm 78$ (s.e.m.) compared with the lower level of 557 ± 162 U released from untreated cells ($P < 0.01$).

Possible explanations for the increased collagenase

Table 1 Collagenase activity in cell culture medium from human fibroblasts

Cells	Cell dilution* and CB addition	Cumulative collagenase during 4 d (U†)
Normal (line 236)	Zero (no CB)	658
	1:1 (CB, 1 µg ml ⁻¹)	2,967
	1:3 (no CB)	580
Normal (line 235)	Zero (no CB)	270
	1:1 (CB, 1 µg ml ⁻¹)	3,234
	1:3 (no CB)	413
Hurler	Zero (no CB)	1,455
	1:1 (CB, 1 µg ml ⁻¹)	5,357
	1:3 (no CB)	1,805

The number of cells initially seeded into the dishes did not change the collagenase activity markedly, but the additional of CB (1 µg ml⁻¹) produced a large increase with all three types of cells. See text and the legend to Fig. 1 for experimental details and assay conditions.

* Disaggregated cells (2 × 10⁵ cells per ml in DMEM with 10% FCS) were plated in duplicate plastic dishes in the dilution shown. When the dishes with the lowest dilution had reached confluence, serum-free medium was added to each dish and CB was added only to those dishes plated originally at 1:1 dilution.

† 1 Unit = 1 µg collagen degraded per h per mg cell protein.

activity in the medium brought about by CB are numerous, and include increased release of preformed collagenase already stored intracellularly, activation of a zymogen of the enzyme, destruction or blockage of an inhibitor of collagenase secreted by the cells, and (or) an increased *de novo* synthesis of collagenase. The following experiment, one of several essentially similar experiments, was carried out to show whether untreated cells had more enzyme stored intracellularly than treated cells, and to test the dependence of collagenase release on new protein synthesis. Six dishes were inoculated with rabbit synovial cells (twelfth passage); three of these were exposed to CB (1.0 µg ml⁻¹). Cycloheximide (Sigma) was added to one control and to one CB-treated dish after collection of medium on day 2 of culture. After medium was collected on day 4, the cells of each dish were washed, dispersed and a portion was counted. The remaining cell suspension was frozen and thawed rapidly (×4) and assayed for collagenase, as was the culture medium from each dish. Table 2 shows clearly that cycloheximide diminished the collagenase production in the treated cells (by more than 90%); enzyme activity in the medium from control cultures was very weak and too near baseline values to make comparisons among dishes. Little difference was found in collagenase activity between control and CB-treated cell lysates.

There is evidence that latent collagenase in culture medium from fibroblasts can be activated by incubation

Table 2 Effect of cycloheximide on stimulation of collagenase by CB

		Collagenase in medium (U*)		Collagenase in cell lysate (U*)
		Days 0-2	Days 2-4	
Control cells	1	107	234	387
	2	49	87	181
	3	140	98†	157‡
CB-treated cells	1	2,018	2,196	372
	2	2,150	1,916	270
	3	2,506	226†	160‡

Rabbit cells were grown for 4 d with or without CB, and one dish from each group was also treated with cycloheximide (10 µg ml⁻¹) during the second 2-d culture period. Cell lysates were prepared at the end of the 4-d period.

* 1 Unit = 1 µg collagen degraded per 10 h per 10⁶ cells.

† Cycloheximide during days 2-4 of culture. Cycloheximide (1-100 µg ml⁻¹) had no effect on collagenase activity when added directly to assays.

‡ Cell lysates from cells to which cycloheximide had been added during culture days 2-4.

with small amounts of trypsin⁵. Whether this signifies the presence of a zymogen, such as that reported for the collagenase in tadpole tails⁸, mouse bone⁹ and polymorphonuclear leukocytes^{10,11}, or destruction or saturation of inhibitory substances^{12,13} is not known. To test the possibility that CB activated a zymogen or inactivated inhibitors in these cultures, media pools from six CB and six control cultures of rabbit synovial fibroblasts (fourteenth passage) were incubated with crystalline trypsin (0.5 µg trypsin per 8.5 µg medium protein) for 1 h at 37 °C. An excess of soy bean trypsin inhibitor was then added and aliquots of each sample were assayed in quadruplicate. The following results (expressed as c.p.m. ¹⁴C-collagen solubilised per 10 h per ml) were obtained: control (no trypsin), 3.4; control (trypsin), 4.1; CB (no trypsin), 870; CB (trypsin), 1,207. Viscometric analysis (27 °C) of the trypsin-activated CB medium with subsequent electrophoresis on polyacrylamide gels revealed typical cleavage of soluble collagen into A (75%) and B (25%) fragments. Similar data have been obtained in other experiments, and we suggest, therefore, that at least a part of the collagenase activity stimulated by CB may be latent in a zymogen or inhibited form.

The precise mechanism by which CB stimulates the production of both active and latent collagenase is unknown, but our results support the idea that the important determinants which, when triggered, activate collagenase production and release by cells are located in cell membranes. Studies underway in our laboratory showing that aminophyllin stimulates collagenase release from fibroblasts (unpublished results of E. Cartwright, E. D. H. and J. J. R.) may implicate cyclic nucleotides in the control of the synthesis and release of non-lysosomal enzymes. Whatever the precise mechanism of action of CB, its use with human and animal cell cultures will be valuable for investigating the role of collagenases in connective tissue diseases.

Induction of synthesis of bacterial protein by excretory product of the alga *Chlamydomonas reinhardtii* γ-1

MANY examples are known of interspecies relationships between widely different organisms in natural communities¹. The benefits that one or more members of a population obtain as a result of their association have been described

mainly in terms of the nutritional value of the relationship, measured in terms of growth rate, metabolic activities, or the ability to survive in a selective environment¹⁻³. We have discovered an apparent commensal relationship between the alga *Chlamydomonas reinhardtii* y-1 and a bacterium, tentatively identified as a coryneform bacterium. As a result of their association, the synthesis of a single protein is stimulated to a remarkable extent within the bacterial cells, whereas the algal cells apparently obtain neither benefit nor detriment from the relationship.

This discovery was facilitated by the observation that ³H-leucine (40–60 Ci mmol⁻¹), when added to mixed cultures of these two organisms to a concentration near 10⁻⁷ M, is selectively incorporated only into proteins synthesised within the bacterial cells. Figures 1 and 2 show the electrophoretic patterns of radioactivity obtained after ³H-leucine was added to pure, dark-grown cultures of the bacteria (Fig. 1a) and *C. reinhardtii* y-1 (Fig. 1b), and to a mixed, dark-grown population of both organisms (Fig. 2) after 1 h of exposure to light. Very little radioactivity was

Fig. 1 Electrophoretic analysis of the incorporation of ³H-leucine into total polypeptides of bacteria (a) and *C. reinhardtii* y-1 (b), each grown separately in pure culture. Bacterial cells were grown in the dark in the algal medium⁶ containing 0.5% yeast extract and 0.5% peptone. The cells were washed twice and resuspended in the algal medium to a density of 0.1A₄₅₀. Dark-grown cells of both organisms were exposed to light for 1 h, and ³H-leucine (4 μCi ml⁻¹) was added to each culture. After 1 h incubation cells from each culture were collected by centrifugation. Bacterial cells were incubated for 45 min in 25 mM Tris-HCl (pH 7.6) containing 1 mM EDTA, lysozyme 0.25 mg ml⁻¹, and chloramphenicol 25 μg ml⁻¹. In these conditions the bacterial cells swell but do not lyse. The cells were collected by centrifugation and frozen. Procedures for electrophoresis of total cellular proteins and for determination of the patterns of radioactivity were as described¹²⁻¹⁴.

Fig. 2 Electrophoretic analysis of the incorporation of ³H-leucine into total polypeptides of a mixed population of bacterial and algal cells labelled in the light. Bacteria were grown as described in Fig. 1 and mixed with etiolated cells of *C. reinhardtii* y-1. The mixed population was exposed to light for 1 h, and incubated for an additional 1 h with ³H-leucine (4 μCi ml⁻¹) in the light. Cells of both organisms were incubated with lysozyme and total proteins were prepared for electrophoresis as described in Fig. 1.

detected in gels containing total proteins of the algal cells grown in pure culture (Fig. 1b). With the exception of a single polypeptide fraction (arrows), however, the pattern of total radioactivity for the bacterial cells alone (Fig. 1a) resembled that for mixed cells (Fig. 2). This incorporation of leucine by the bacterial cells was resistant to the action of cycloheximide, but was nearly abolished by inhibitors of 70S ribosomes⁴. Furthermore, the incorporation was blocked by inhibitors of prokaryotic RNA synthesis⁴.

Leucine seems to be poorly transported across the plasma membrane of *C. reinhardtii*, as a several hundredfold increase in the extracellular concentration of this amino acid was required to obtain significant labelling of the algal proteins⁴. The resulting pattern of radioactivity for algal cells labelled with ³H-leucine (1 Ci mmol⁻¹, 3 × 10⁻³ M in the medium) bore no resemblance to the bacterial pattern shown in Fig. 1a.

The prominent peak of radioactivity in the pattern for mixed cultures (Fig. 2, arrow) corresponds to a polypeptide

with a molecular weight of about 21,500. Synthesis of this polypeptide within the bacterial cells was observed when dark-grown cultures of a mixed population of bacterial and algal cells was exposed to light (Fig. 2), but was not observed when a mixed culture was labelled in the dark (Fig. 3) without exposure to light. Nor was this polypeptide synthesised when dark-grown bacterial cells were exposed to light in the absence of the algal cells (Fig. 1a), suggesting that the photoreceptor for synthesis of this polypeptide resides within the algal cells. Thus, the absorption of light by etiolated cells of *C. reinhardtii* y-1 elicits a response that stimulates the synthesis of a single protein within this bacterium as the result of their association.

Algae are known to excrete a wide variety of substances⁵⁻⁷, and commensal relationships have been reported in which the growth of bacteria depended on the excretion of oxidisable substrates by algal cells³. To test for excretion of an inducing substance by *C. reinhardtii* y-1, a pure culture of dark-grown algal cells was exposed to light, and after 90 min of illumination, the algal cells were removed by centrifugation. Synthesis of the inducible protein was

Fig. 3 Electrophoretic analysis of the incorporation of ³H-leucine into total polypeptides of a mixed population of bacterial and algal cells labelled in the dark. Dark-grown cells of both organisms were mixed and incubated with ³H-leucine (4 μ Ci ml⁻¹) for 1 h without exposure to light. After treatment with lysozyme, total proteins of the cell mixture were prepared for electrophoresis as described in Fig. 1.

stimulated when the bacteria were suspended in this medium. No induction of the synthesis of this protein, however, was detected when the bacteria were suspended in medium obtained in the same way from a mixed population of the two organisms. These results indicated that in response to light the etiolated algal cells released a limited amount of the inducing factor into the medium, and that this factor was quantitatively used by the bacterial cells.

Although we have not identified this factor, its production may be related to the breakdown of starch in etiolated *C. reinhardtii* y-1. In this alga, starch breakdown requires continuous illumination and is maximal during the lag phase of chlorophyll synthesis⁸. The time course of synthesis of the inducible protein within the bacteria during continuous illumination of mixed cultures also reached a maximum during the lag phase of chlorophyll synthesis. Thereafter, the rate declined until synthesis of this protein was barely detectable when the algal cells had become fully green (data to be published elsewhere).

The coryneform bacteria contain a large number of plant saprophytes found in soil and water environments⁹⁻¹¹. Many species within this group require vitamins and other essential organic molecules that are normally obtained from their natural habitats⁹⁻¹¹. The coryneform bacteria used in these studies were isolated as contaminants of our y-1 strain of *C. reinhardtii*. They grow poorly in the defined algal medium containing acetate as a carbon source⁸, and on agar they form transparent colonies not visible to the unaided eye.

The bacteria could not be separated from the algal cells by sucrose gradient or differential centrifugation techniques⁴, because of aggregation of the bacteria in liquid media. Lysozyme treatment was required to lyse the bacteria sufficiently to release proteins for gel electrophoresis. We previously concluded that leucine had selectively entered the mitochondrial pool of amino acids within the algal cells, as the latter do lyse in these conditions without lysozyme treatment⁴.

As we do not know of any benefit derived from synthesis of the inducible protein within the bacteria, at present their relationship with *C. reinhardtii* y-1 must be considered commensal only in so far as one member seems to be affected by the association. True commensalism has been found between bacteria and other algal and yeast cells based on the nutritional requirements of the bacteria^{2,3}. This is the first report, however, that such an interaction may control specific gene expression within one member of the association. Further studies are in progress to determine the identities of the algal induction factor and the protein synthesised by these bacteria in response to this factor.

Kinetics of inactivation of histone mRNA in the cytoplasm after inhibition of DNA replication in synchronised HeLa cells

In many eukaryotic cells DNA replication and histone synthesis proceed synchronously¹⁻⁶. Interruption of DNA synthesis in synchronised HeLa cells results in an immediate decrease of histone synthesis as measured by incorporation of labelled amino acids into histones^{2,3} or by following the completion of nascent histone polypeptide chains on polyribosomes *in vitro*⁵.

Recent long-term labelling experiments by Perry and Kelley⁷ suggest that in mouse L cells the lifetime of histone mRNA is of the order of the length of one S-phase (that is about 11 h). If, however, DNA replication is blocked with cytosine arabinoside or hydroxyurea, labelled histone mRNA selectively disappears from polyribosomes between 30 and 60 min after addition of these drugs to the cells⁵⁻⁷. In contrast, actinomycin D (5 $\mu\text{g ml}^{-1}$) only slightly decreases histone synthesis during the first hour of its action⁸.

Recently we have introduced a method of titrating the amount of biologically active histone mRNA by its transla-

Fig. 1 Inactivation of polyribosomal histone mRNA after termination of DNA synthesis. Thymidine-synchronised cells 3 h in S-phase were treated with 3 mM hydroxyurea for different times and lysed in hypotonic buffer. Polyribosomes were isolated as described¹⁰, resuspended in 35 mM Tris-HCl (pH 7.5), 10 mM EDTA, 0.1 M NaCl, 0.5% sodium dodecyl sulphate and the RNA was extracted with buffer-saturated phenol and phenol-chloroform (1:1, v/v)¹⁰. The RNA was passed over poly(U)-Sepharose equilibrated with 10 mM Tris-HCl (pH 7.5) containing 0.5 M KCl: RNA not adsorbed to poly(U)-Sepharose was fractionated on sucrose gradients and histone mRNA translated in a rabbit reticulocyte lysate as described¹⁰. The amount of mRNA was calculated from the radioactivity incorporated into protein according to the equation $(A-B)/a$; A and B being (c.p.m. in CM-2 $\times 100$)/(c.p.m. in CM-1) from lysates incubated in the presence or absence of histone mRNA, respectively; a being (μg of polyribosomal poly(A)(-)-RNA from which histone mRNA was recovered). Open and closed circles represent data from two separate experiments. The insert is a semi-logarithmic plot of the data.

tional capacity in a rabbit reticulocyte lysate⁹. Using this method we showed that in S-phase of synchronised HeLa cells about 80% of functional histone mRNA was lost from polyribosomes within 60 min of inhibition of DNA synthesis whereas actinomycin D for 1 h only slightly decreased histone mRNA activity⁹. We describe experiments here showing that these RNA species decay from the cytoplasm with an approximate half life of 13 min after interruption of DNA replication with hydroxyurea.

Fig. 2 Polyacrylamide gel electrophoresis of acid-soluble proteins (CM-2 fraction) synthesised in a reticulocyte lysate under the direction of histone mRNA from cells 3 (○) and 4 (●) h in S-phase (a) and from 3-h S-phase cells treated with 3 mM hydroxyurea for 15 min (b), 30 min (c) and 60 min (d, ○). CM-2 proteins from a lysate incubated without added mRNA are represented in d (●). Proteins were dissolved in 6 M urea containing 0.5 M 2-mercaptoethanol, incubated for 30 min at room temperature and electrophoresed in 15% acrylamide gels containing 2.5 M urea¹⁴. Gels were sliced and radioactivity measured as described¹⁰.

HeLa S-3 cells were grown in suspension culture in Eagle's minimum essential spinner medium supplemented with 5% calf serum. Cells were synchronised by a double block with 2 mM thymidine and allowed to enter S-phase by resuspension in fresh medium at a concentration of 3×10^5 – 4×10^5 cell ml^{-1} (ref. 10). Three and four hours after entering into S-phase the cells synthesise histones at maximal rate⁶. Cells were then treated for different times with 3 mM hydroxyurea which results, within less than 5 min, in an inhibition of thymidine incorporation by more than 98%. Polyribosomal RNA was isolated and passed over poly(U)-Sepharose columns to purify it from poly(A)-containing mRNA. Histone mRNA lacking poly(A) at the 3'-OH end¹¹ was then separated on sucrose gradients and quantitated by its translation in a reticulocyte lysate as described previously^{8,9}. Acid-soluble proteins of the lysate were separated by CM-cellulose chromatography into

two fractions, CM-1 which predominantly contains globin and CM-2 containing the histones¹⁰.

From Fig. 1 it can be deduced that as early as 10 min after a blockade of DNA replication about 20% of functional histone mRNA is lost from polyribosomes in comparison to the mRNA content of 3-h S-phase cells. Thirty and 60 min after arrest of DNA synthesis less than 30% and 15% respectively of active histone mRNA are left on polyribosomes. Further treatment with the blocking agent did not change this value significantly. A further increase of polyribosomal histone mRNA by about 20–30% was observed between the third and fourth hour after entry into S-phase which subsequently decreased again (data not shown). It should be pointed out that active histone mRNA does not survive unbound to ribosomes in the cytoplasm after DNA synthesis is stopped^{9,12}.

The gel electrophoretic profiles show that synthesis of all histone fractions is equally inhibited following the block of DNA replication (Fig. 2). It can also be seen in Fig. 2 that CM-2 proteins from reticulocyte lysates incubated without added mRNA contain labelled material which predominantly coelectrophoreses with globin (Fig. 2d, ●, fractions 48–52). Therefore, such control lysates had to be taken into account in the calculation of histone mRNA activity (see legend to Fig. 1).

If it is assumed that after interruption of DNA replication the flow of new histone mRNA from the nucleus to the cytoplasm immediately ceases (as a result of an inhibition of either the transcription of histone genes, the processing of histone mRNA in the nucleus or its transport into the cytoplasm) the disappearance of histone mRNA from the cytoplasm is a function mainly of the degradation (or inactivation) of that RNA. From a semilogarithmic plot of the data presented in Fig. 1 it can be deduced that, after a short lag of about 5 min, histone mRNA is inactivated according to first-order kinetics with a

half life of about 13 min (insert in Fig. 1). The short lag possibly results from the time required for hydroxyurea to penetrate the cells and to interrupt subsequent flow of histone mRNA from the nucleus to the cytoplasm.

Butler and Mueller¹³ recently reported that cycloheximide prevents the inhibition of histone mRNA synthesis by hydroxyurea. We measured the polyribosomal mRNA in cells which were treated with cycloheximide and hydroxyurea simultaneously and found that although DNA replication was completely blocked by the two drugs histone mRNA survived on polyribosomes in these experimental conditions (Fig. 3). Since cycloheximide 'freezes' polyribosomal structures this study indicates that histone mRNA in cells treated in this manner is protected from degradation by its binding to ribosomes. This implies that a step in the initiation of histone mRNA translation may be inhibited in the absence of DNA replication so that the mRNA becomes susceptible to cellular nuclease(s). Alternatively, the inactivation of histone mRNA in the cytoplasm after cessation of DNA synthesis could be linked in some unknown manner to a process depending on protein synthesis.

The extremely short half life of histone mRNA in the absence of DNA replication described here is consistent with the data presented by Perry and Kelley⁷ which indicate that in mouse L cells the decay of histone mRNA increases nearly linearly with the age of these RNA species. From all the known experimental results it is now well substantiated that histone mRNA is present on polyribosomes only during the DNA replication period of the cell cycle^{5-7,10,12,15}. These RNA species are synthesised during the first few hours of S-phase starting with the initiation of DNA replication^{6,10}, they are stable during S-phase⁷ and are destroyed with a half life of about 13 min after termination of DNA synthesis. The shut-down of histone synthesis at the end of S-phase is therefore the consequence of an inactivation of cytoplasmic histone mRNA which seems to involve a specific translational control mechanism operating at the initiation of histone mRNA translation.

I thank Mrs R. Seidel for technical assistance. This investigation was supported by the Deutsche Forschungsgemeinschaft.

Fig. 3 Effect of cycloheximide on hydroxyurea-induced inactivation of histone mRNA. 600-ml spinner cultures of synchronised cells 3 h in S-phase were untreated (a) or treated for 45 min with either 3 mM hydroxyurea (b), 10 μM cycloheximide (c) or with both drugs simultaneously (d). In the latter case cycloheximide was added to the cultures 3 min before hydroxyurea. Two minutes before collecting the cells, cycloheximide was also added to cultures a and b. The data represent two separate experiments.

In vitro transcription of a late class of phage SP01 genes

Bacillus subtilis phage SP01 directs the synthesis of at least six temporally defined classes of phage-specified transcripts¹. Synthesis of the two earliest classes of phage RNA (e and em) does not require phage protein synthesis, while the synthesis of middle (m and m₁) and late (m₂ and l) transcripts requires the protein product of regulatory gene 28 and the products of regulatory genes 33 and 34, respectively^{2,3}. The discovery of SP01-induced polypeptides associated with *B. subtilis* RNA polymerase suggested that the products of SP01 regulatory

genes could control transcription by interacting directly with the host RNA polymerase^{4,5}. In support of this idea, we reported⁶ that a form of RNA polymerase from SP01-infected cells copies middle RNA almost exclusively from the heavy (H) strand of native SP01 DNA, the DNA strand from which middle and late genes are transcribed *in vivo*. This enzyme contains an SP01-induced polypeptide termed IV (molecular weight 26,000) that is now known to be the product of regulatory gene 28 (T. Fox, R. L. and J. P., manuscript in preparation). Accurate middle gene transcription by this phage-modified RNA

polymerase does not require σ factor but is apparently dependent on a newly described host subunit of RNA polymerase called δ (molecular weight 21,500)⁶. Other workers have also reported the preferential synthesis of middle RNA by RNA polymerase from phage-infected *B. subtilis*^{7,8}. Here we report that in the presence of host δ protein a form of RNA polymerase containing phage-induced polypeptides termed V (molecular weight 24,000) and VI (molecular weight 13,500) asymmetrically transcribes a class of SP01 late genes *in vitro*.

Two forms of RNA polymerase designated enzymes B and C were purified from SP01-infected bacteria as previously described⁶. In addition to the subunits of core RNA polymerase (β' , β , α and ω), enzyme C contained phage-induced subunits V and VI, while enzyme B contained phage-induced subunit IV and traces of VI (Fig. 1). Both enzymes lacked the host δ protein and copied RNA with only a small preference for the H strand of native SP01 DNA (Fig. 2). In the presence of δ protein purified from uninfected bacteria (Fig. 1), however, enzymes B and C copied RNA predominantly from strand H (the H/L hybridisation ratios increased from 1.7 to 9.4 and from 1.2 to 8.6, respectively; Fig. 2). As previously reported⁶, δ had little effect on the strand selectivity of transcription by core enzyme from uninfected cells (the H/L ratio increased from 1.2 to 2.0; data not shown). Thus in the presence of δ ,

Fig. 1 SDS polyacrylamide slab gel electrophoresis of enzyme B, enzyme C, δ and σ . Enzymes B and C were purified as described previously⁶. δ and σ were dissociated from purified holoenzyme⁹ from uninfected *B. subtilis* by chromatography on phosphocellulose⁹, dialysed against buffer C (ref. 4) containing 0.01 M EDTA and 0.02 M KCl, and then applied to a poly(C)-cellulose column¹⁰. δ eluted in the flow-through while σ , which adhered to the column, was eluted with buffer containing 8 M urea. Electrophoresis was on a 25-cm long slab gel containing sodium dodecyl sulphate in a Tris-glycine buffer and a 7–15% gradient of polyacrylamide¹¹.

Fig. 2 Effect of δ on the strand selectivity of transcription by enzymes B and C. Radioactive RNA was synthesised *in vitro* by 3.5 μ g of enzyme B and 2.0 μ g of enzyme C in the absence (open symbols) and presence (closed symbols) of 0.4 μ g of purified δ (Fig. 1). Hybridisation reactions contained the indicated amounts of H strand (\square , \blacksquare) and L strand (\circ , \bullet) DNA and the following 3 H-RNAs in 125 μ l of $2 \times$ SSC: a, RNA synthesised by enzyme B (\square , \circ) (input, 25,200 c.p.m.; background, 490 c.p.m.); RNA synthesised by enzyme B + δ (\blacksquare , \bullet) (input, 22,700 c.p.m.; background, 1,100 c.p.m.). b, RNA synthesised by enzyme C (\square , \circ) (input, 14,500 c.p.m.; background, 540 c.p.m.); RNA synthesised by enzyme C + δ (\blacksquare , \bullet) (input, 11,700 c.p.m.; background, 280 c.p.m.). The experimental procedures for the synthesis of RNA, preparation of DNA strands and the hybridisation of RNA were described previously⁶.

enzymes B and C directed highly asymmetric transcription of SP01 DNA.

Since enzymes B and C contained different phage-induced polypeptides, it seemed possible that in the presence of host δ protein each phage-modified RNA polymerase was transcribing asymmetrically a different class of SP01 genes. To compare the classes of RNA synthesised by enzyme B + δ and enzyme C + δ , radioactive RNA synthesised *in vitro* was hybridised to denatured SP01 DNA in the presence of unlabelled RNA from cells collected at early (CAM), middle (10') and late (30') times in the lytic cycle. (The early RNA was purified from cells that had been treated with chloramphenicol to block phage protein synthesis.) The experiment of Fig. 3c shows that the hybridisation of RNA synthesised by enzyme B + δ was more effectively

Fig. 3 Hybridisation competition of ^3H -RNAs by competitor RNAs isolated at various times after infection. Hybridisation reactions contained 2.5 μg of denatured SP01 DNA, the indicated amounts of unlabelled competitor RNAs and the following ^3H -RNAs in a total volume of 200 μl of $2\times\text{SSC}$. *a*, Middle SP01 RNA pulse labelled *in vivo* 8–10 min after infection; 33% of the input RNA (21,000 c.p.m.) hybridised in the absence of competitor. *b*, Late SP01 RNA pulse labelled *in vivo* 27–29 min after infection; 18% of the input RNA (23,000 c.p.m.) hybridised in the absence of competitor. *c*, RNA synthesised *in vitro* by enzyme B+ δ ; 39% of the input RNA (9,800 c.p.m.) hybridised in the absence of competitor. *d*, RNA synthesised *in vitro* by enzyme C+ δ ; 61% of the input RNA (11,200 c.p.m.) hybridised in the absence of competitor. *e*, RNA synthesised *in vitro* by core polymerase from uninfected *B. subtilis*; 50% of the input RNA (8,100 c.p.m.) hybridised in the absence of competitor. *f*, RNA synthesised *in vitro* by enzyme C; 49% of the input RNA (11,600 c.p.m.) hybridised in the absence of competitor. For each reaction a background of less than 3% of the input was subtracted from the radioactivity that was retained in hybrid. CAM (■) RNA was from bacteria treated with 150 μg of chloramphenicol before infection; 10' (□) RNA and 30' (●) RNA were from cells collected 10 and 30 min after infection, respectively. These competitors were prepared as described previously¹². The experimental procedure for the labelling of RNA *in vivo*, for the synthesis of labelled RNA *in vitro* and for hybridisation of radioactive RNA was as described previously⁶.

inhibited by middle RNA than by the late or early competitors. In fact, the RNA competitors similarly affected the hybridisation of *in vivo* synthesised RNA radioactively labelled at a middle time in the lytic cycle (Fig. 3a). In contrast, the hybridisation of RNA synthesised *in vitro* by enzyme C+ δ was more effectively competed by late RNA than by the middle or early competitors (Fig. 3d); and this competition pattern was similar to that obtained for RNA labelled *in vivo* at a late time in the lytic cycle (Fig. 3b). As further evidence that enzyme C+ δ was preferentially synthesising a class of late RNA, we found that RNA extracted at a late time after infection by a gene 34 mutant was a poor competitor of the *in vitro* product of enzyme C+ δ (data not shown). (This mutant phage fails to synthesise late transcripts m_2 and l (refs 2 and 3).) The specific transcription of SP01 late genes *in vitro* requires the host δ protein since enzyme C alone copied RNA symmetrically (Table 1, ref. 6) from both strands of native phage template (Fig. 2b) and since the hybridisation of RNA synthesised by enzyme C alone was not preferentially competed by late RNA (Fig. 3f). It should be noted, however, that our experiments do not distinguish whether enzyme C+ δ copies all late transcripts (m_2 and l) or only a limited set of late sequences.

Which, if any, of the phage-induced polypeptides present in enzymes B and C direct the transcription of middle or late genes *in vitro*? Enzyme B contains phage-induced subunit IV and traces of subunit VI. It is likely that subunit IV causes the synthesis of middle transcripts (m and/or m_1) *in vitro* since polypeptide IV is now known to be coded by gene 28 (T. Fox, R. L. and J. P., manuscript in preparation), the regulatory gene whose product is necessary for middle gene transcription *in vivo*^{2,3}. While polypeptide IV is synthesised early in the phage lytic cycle, as would be expected of a protein that directs middle gene transcription, polypeptides V and VI first appear at a middle time in the lytic cycle (ref. 4 and T. Fox, unpublished results), a finding consistent with the idea that either or both of these proteins could direct late transcription by enzyme C. A reconstitution experiment with the isolated subunits IV, V and VI will, however, be required to prove that these phage-induced proteins direct specific gene transcription.

Escherichia coli RNA polymerase purified from phage T4-infected bacteria also contains phage-induced polypeptides¹³. Two of these proteins are coded by T4 genes 33 and 55, regulatory genes whose products direct late T4 transcription *in vivo*^{14,15}. Purified *E. coli* RNA polymerase containing these phage-induced subunits does not, however, specifically direct late transcription *in vitro*¹⁶. This could result from the apparent coupling of late transcription to DNA synthesis *in vivo*^{17,18}. It is also possible, however, that late transcription by the T4-modified polymerase requires an unidentified *E. coli* protein equivalent to *B. subtilis* δ in addition to T4 regulatory proteins.

In conclusion, the finding of specific transcription of SP01 middle and late genes by RNA polymerase containing phage-induced subunits supports a model of positive control elaborated by Travers¹⁰ in which phage regulatory proteins direct specific transcription by interacting with RNA polymerase in place of the host σ factor.

We thank T. Fox for helpful discussions, D. Ratner for critical reading of the manuscript and G. Carmichael for poly(C)-cellulose. This work was supported by a US National Science Foundation grant.

N⁶, O²-dimethyladenosine a novel methylated ribonucleoside next to the 5' terminal of animal cell and virus mRNAs

MODIFIED 5'-terminal structures of the type m⁷G(5')ppp(5')Nm have been identified in various viral^{1–4} and cellular^{5–8} mRNAs. The 5'-terminal modification of mRNA may be carried out by specific guanylyl- and methyltransferases⁹ and the structure seems to be required for efficient *in vitro* translation¹⁰. Studies⁵

Fig. 1 Paper chromatography of methylated ribonucleosides from 5'-terminal oligonucleotides of: *a*, HeLa cell mRNA; *b*, mouse L cell mRNA; and *c*, adenovirus mRNA. Cells were labelled for 4 h with methyl-³H methionine, and polyadenylated mRNA was isolated from the cytoplasm by poly(U)-Sephadex chromatography as previously described⁵. Polyadenylated mRNA from the cytoplasm of adenovirus-infected HeLa cells was also selected by hybridisation to adenovirus DNA (B.M. and F. Kocot, unpublished). After hydrolysis of HeLa and L cell mRNAs with RNase T2, T1 and A and adenovirus mRNA with 0.4 N KOH the 5'-terminal oligonucleotides were isolated by DEAE-cellulose chromatography as the –5 to –6 charge peak⁶. The desalted 5'-terminal oligonucleotides were then digested to their constituent ribonucleosides by a combination of venom phosphodiesterase and alkaline phosphatase. The digest was analysed by ascending paper chromatography with solvent containing *n*-butanol–concentrated NH₃–H₂O (86:5:14).

of the 5'-terminal sequences of HeLa cell mRNAs revealed a methylated nucleoside that chromatographed slightly ahead of 2'-O-methyladenosine (Am). We have now identified this novel nucleoside and found that it is common to mRNAs of human and mouse cells as well as at least one virus.

The 5'-terminal oligonucleotides obtained by alkali or RNase digestion of HeLa cell mRNAs have the structures m⁷G(5')ppp(5')NmpNp and m⁷G(5')ppp(5')NmpNmpNp and elute from DEAE-cellulose columns with net charges of –5 to –6 (refs 5 and 7). Figure 1 shows a nucleoside analysis of the 5'-terminal oligonucleotides from methyl-³H-methionine-labelled mRNAs of HeLa cells, mouse L cells and adenovirus grown in HeLa cells. In addition to 7-methylguanosine (m⁷G) and the four common 2'-O-methylribonucleosides (Gm, Um, Cm and Am), a major component of each mRNA chromatographed between Am and N⁶-isopentenyladenosine (iA). The unusual nucleoside was designated A*m and tentatively considered to be a derivative of adenosine since it comigrated on electrophoresis with adenosine and Am in 1 M formic acid (Fig. 2). A*m was further shown to lack *cis*-hydroxyls by borate electrophoresis at pH 9 (ref. 5) and therefore seemed to be a derivative of Am with an additional base modification. The following experiment was designed to test whether the base was methylated and if so to identify it.

Fig. 2 Thin-layer electrophoresis of A*m. Methyl-³H-labelled A*m was isolated by paper chromatography as in Fig. 1a and analysed by electrophoresis on a thin layer of cellulose in 1 M formic acid at 800 V for 70 min.

The 5'-terminal oligonucleotides of HeLa cell mRNA were isolated and digested with P₁ nuclease (an enzyme that hydrolyses RNA to 5'-nucleotides and is not inhibited by 2'-O-methylribonucleosides¹¹) and nucleotide pyrophosphatase (an enzyme that cleaves m⁷GpppNm to pm⁷G, pNm and Pi²) to liberate methyl-labelled pA*m. The latter comigrated with pA on paper electrophoresis at pH 3.5, further suggesting that the novel compound is a derivative of adenosine. The isolated pA*m along with a small amount of contaminating pAm was then treated with 1 N HCl at 100 °C to liberate the free base. Slightly more than half of the methyl-labelled material co-chromatographed with N⁶-methyladenine (m⁶Ade) while the remainder, presumably the degradation product of 2'-O-methylribose phosphate, stayed at the origin (Fig. 3a). Since no alkaline step was used in this procedure it is unlikely that m⁶Ade was derived by rearrangement of m¹Ade. Some apparent loss of the 2'-O-methylribose derivative resulted from the lability of the O-methyl bond in 1 N HCl at 100 °C. As a control experiment, methyl-labelled pAm was isolated from the 5'-terminus of vaccinia virus mRNA¹ and treated similarly. The methyl-labelled material remained at the origin and none chromatographed as m⁶Ade (Fig. 3b).

Further evidence that the modified base of A*m is m⁶Ade was obtained by labelling HeLa cell mRNA with 2,8-³H-adenosine. Combined P₁ nuclease and alkaline phosphatase digestion followed by adsorption of the enzyme-resistant

material to a DEAE-cellulose column was used to separate the 5'-terminal oligonucleotide containing A*m from all but a small amount of the thousandfold or greater excess of internal adenosine residues. Nucleoside analysis indicated incorporation of radioactive isotope into A*m (Fig. 4a). The purified 2,8-³H-A*m was then treated with 1 N HCl at 100 °C and the labelled base released was identified as m⁶Ade in three different chromatographic systems, one of which is shown in Fig. 4b.

The sugar moiety of A*m was also characterised by cleaving methyl-³H-A*m with spleen purine nucleoside phosphorylase (Sigma) in the presence of phosphate. The labelled product cochromatographed, on a thin-layer cellulose sheet in ethyl acetate, isopropanol, 7.5 M NH₄OH, *n*-butanol (3:2:2:1), with 2-O-methylribose-1-phosphate derived from authentic Am (not shown). In the latter experiment radioactivity was lost from the methylated base because of the deaminase activity associated with nucleoside phosphorylase¹².

We conclude that the novel nucleoside found in HeLa cell, L cell and adenovirus mRNAs is N⁶,O^{2'}-dimethyladenosine (m⁶Am). Furthermore, m⁷G(5')ppp(5')m⁶Am is the major 5'-terminal sequence of the type m⁷G(5')ppp(5')Nm in both HeLa cell mRNAs, where it comprises about 20–30% of the total (C.-M.W., A.G. and B.M., unpublished), and adenovirus mRNAs, where it comprises 80% of the total (B.M. and F. Koczot, unpublished). In addition both Adams and Cory⁶ studying mouse myeloma cell mRNA, and Moyer *et al.*¹³ studying vesicular stomatitis virus mRNA synthesised *in vivo* noted an unidentified nucleoside adjacent to m⁷G which they suspected was a derivative of Am with a modified base. By contrast m⁶Am is definitely not present in either vaccinia virus¹ or vesicular stomatitis virus⁴ mRNAs synthesised *in vitro* by virion-associated enzymes, suggesting that a cellular methyltransferase is used. This methyltransferase must be quite specific since m⁶Am has not been identified in either tRNA or rRNA. A recent report¹⁴, however, indicates that an internal

Fig. 3 Identification of methylated base. *a*, Methyl-³H-labelled 5'-terminal oligonucleotides of HeLa cell mRNA were isolated as in Fig. 1a and successively digested with 100 µg of nuclease P₁ in 200 µl of 10 mM sodium acetate; pH 6, at 37 °C for 1 h and 0.2 U nucleotide pyrophosphatase in 20 mM Tris-HCl, pH 7.6, 1 mM MgCl₂ at 37 °C for 30 min. The ribonucleotides were separated by electrophoresis on a 40 cm sheet of Whatman 3 MM paper in 50 mM ammonium formate, pH 3.5, 1 mM EDTA at 1,900 V for 3 h. The fractions corresponding to adenylic acid marker and containing pA*m were pooled. pA*m was heated with 1 N HCl at 100 °C for 30 min and the product was analysed by ascending paper chromatography with solvent containing *n*-butanol-concentrated NH₃-H₂O (86:5:14). *b*, Methyl-³H-labelled pAm isolated from vaccinia virus mRNA¹ was treated with 1 N HCl and similarly analysed.

Fig. 4 Incorporation of 2,8-³H-adenine into N⁶-methyladenine moiety of A*m. *a*, HeLa cells (4 × 10⁸) were incubated in 1 l of medium containing 20 µM guanosine and 10 mCi (40.8 Ci mmol⁻¹) of 2,8-³H-adenosine for 24 h at 37 °C. The cytoplasmic polyadenylated mRNA was isolated as in Fig. 1 and then digested with nuclease P₁ (50 µg per 100 µl) in 10 mM sodium acetate, pH 6, at 37 °C for 1 h and then with alkaline phosphatase (10 µg per 100 µl) in 50 mM Tris-HCl, pH 8.5, 5 mM MgCl₂ at 37 °C for 2 h. The diluted digest was applied to a 5 ml DEAE-cellulose column equilibrated with 25 mM ammonium acetate and then extensively washed with 25 mM ammonium acetate. The labelled m⁷G(5')ppp(5')Nm was eluted with 1 M ammonium acetate, lyophilised and digested with venom phosphodiesterase and alkaline phosphatase. The nucleosides were analysed by ascending paper chromatography with solvent containing *n*-butanol-concentrated-NH₃-H₂O (86:5:14). *b*, Identification of 2,8-³H-N⁶-methyladenine. Labelled A*m isolated by paper chromatography as indicated above (*a*) was treated with 1 N HCl at 100 °C for 30 min and analysed by thin-layer chromatography with solvent containing isopropanol-concentrated HCl-H₂O (680:144:170).

m⁶Am residue is present in a low molecular weight nuclear RNA. It is possible that m⁶Am has a role in protein synthesis since in mRNAs it lies adjacent to the m⁷G residue that is required for efficient translation of certain mRNAs *in vitro*¹⁰.

We thank A. Kuninaka for P₁ nuclease, F. Koczot for labelled adenovirus mRNA and W. K. Joklik for L cells.

Two distinct mechanisms of synthesis of DNA fragments on colicin E1 plasmid DNA

REPLICATION of closed-circular colicin E1 plasmid (Col E1) DNA can be initiated and completed in extracts of *Escherichia coli*^{1,2}. The major products of *in vitro* replication are completely replicated molecules (23S) and a unique type of early replicative intermediate (26S) containing a newly synthesised DNA fragment(s) in a small replication loop. The fragment has an average length of approximately one fifteenth of the unit length of the plasmid molecule and has a sedimentation constant of approximately 6S^{1,3}. The replicated region of the intermediate consists of either one double-stranded branch and one single-stranded branch (type I) or two double-stranded branches (type II)^{2,4}. These intermediates accumulate in a reaction mixture containing 10% glycerol^{2,3}. Synthesis of the intermediates is inhibited by rifampicin^{1,3} but most of the intermediates can complete replication in the presence of rifampicin³. Rifampicin is also known to inhibit *in vivo* replication of Col E1 DNA⁵. We have studied the synthesis and fate of 6S DNA fragments formed on the parental heavy (H) strands and those formed on the parental light (L) strands (defined by CsCl density gradient centrifugation in the presence of poly(U,G)) of early replicative intermediates. The results show that the first synthesis of a DNA fragment is initiated at a specific site on the H strand and depends on the function of

Fig. 1 Alkaline sucrose gradient centrifugation patterns of ³²P-labelled early replicative intermediates before (a) and after incubation in a cell extract with rifampicin (b). A portion of sample C (unheated) in Table 1 was centrifuged in an alkaline sucrose gradient (5–20%) at 45,000 r.p.m. for 2 h at 5 °C in a Beckman SW 50.1 rotor¹. Fractions were collected from the tube bottom. The pattern of distribution of radioactivity is shown in (a). Another portion of sample C (unheated) was incubated for 90 min at 30 °C in the standard reaction mixture¹ containing an extract of YS1 cells and rifampicin (10 µg ml⁻¹) without glycerol and spermidine. DNA was extracted and similarly centrifuged (b). The reference DNAs were, from the left, ³H-labelled collapsed closed-circular Col E1 DNA and circular and linear DNA of the unit length. —, ³²P; ---, ³H.

Fig. 2 Distribution of radioactivity in strands of completely replicated molecules derived from early replicative intermediates with ³²P-labelled 6S DNA. The DNA formed by incubation of sample C as described in the legend to Fig. 1b was centrifuged after heating at 90 °C for 90 s in neutral sucrose gradient (5–20%) at 45,000 r.p.m. for 150 min at 10 °C in a SW 50.1 rotor¹. Completely replicated closed-circular molecules (23S) thus isolated were converted to the linear form by treating with endonuclease *EcoRI*⁴. The linear molecules were denatured and centrifuged in a CsCl density gradient containing poly(U,G) and fractionated as described⁶. The reference DNAs were, from the left, H strands and L strands of Col E1 DNA. —, ³²P; ---, ³H

E. coli DNA-dependent RNA polymerase. Subsequent synthesis of the DNA fragment on the L strand does not involve the RNA polymerase.

To examine whether or not the strand in the type I intermediates was specifically synthesised on one of the parental strands, early replicative intermediates with 6S fragments labelled, *in vitro*, with α-³²P-dTMP were prepared (Table 1). Samples A and B were made after incubation for 10 or 45 min at 30 °C of a reaction mixture with a freshly prepared cell extract; sample C was made from a reaction mixture incubated for 45 min with a cell extract stored for 1 week at –20 °C. After purification of ³²P-labelled replicative intermediates³, labelled 6S DNA was separated from the parental strands by heating at 90 °C for 90 s (ref. 3) and then annealed with separate H and L strands of Col E1 DNA fixed on membrane filters. Table 1 shows that in all cases more labelled 6S fragments were hybridised to H strands than L strands. Synthesis of two types of 6S fragments was more asymmetrical for the molecules labelled for 10 min than for 45 min. It was also more asymmetrical for the molecules synthesised with the stored extract than with the fresh extract. In sample B, 33% of 6S fragments was hybridisable to L strands, while about 40% of such a preparation of intermediates was type II as examined electron microscopically². These results show that most type I intermediates had a 6S L fragment.

Formation of early replicative intermediates is sensitive to rifampicin, but most of the intermediates formed in a cell extract can complete replication during continued incubation after addition of rifampicin³. These results indicate either that no further products of the rifampicin-sensitive reaction were necessary for completion of replication of the intermediates, or that products formed before addition of rifampicin could be used for the replication that took place after addition. The validity of these interpretations was tested by examining replication of exogenously added early replicative intermediates in the presence of rifampicin. The preparation of the intermediates (sample C of Table 1) used for this purpose was practically free from labelled, completely replicated molecules as shown by alkaline sucrose density gradient centrifugation of the preparation (Fig. 1a). By contrast, the labelled DNA extracted after the incubation of the intermediates in the presence of rifampicin contained approximately 55% collapsed closed-circular molecules and 10% unit-length single strands (Fig. 1b). Completely replicated molecules were formed from

the early replicative intermediates also in the presence of antibody against *E. coli* RNA polymerase which inhibited formation of the intermediates (data not shown). To test whether type I intermediates replicate in the presence of rifampicin, the distribution of radioactivity between H and L strands of completely replicated molecules derived from the intermediates was examined. After conversion of the molecules to the linear form by treating with endonuclease *EcoRI*⁴, the single strands of the molecules were centrifuged in a CsCl density gradient containing poly(U,G)⁶. The labelled DNA was distributed in L and H strands at the ratio of approximately 6:1 (Fig. 2). If only the type II intermediates completed replication or if labelled DNA was degraded and labelled material was reincorporated into closed-circular molecules, the radioactivity would have been distributed almost equally between the complementary strands of the molecules. The unequal distribution of radioactivity between the complementary strands indicates that the type I intermediates containing a 6S fragment on the parental H strand were converted to completely replicated molecules, in the presence of rifampicin. These results indicate that the product synthesised in the extract by *E. coli* RNA polymerase is not necessary for completion of replication of the intermediates.

Table 1 Strand-specificity of 6S DNA in early replicative intermediates

DNA fixed on filter ³² P-DNA	³² P-DNA hybridised (c.p.m.)		³² P-DNA applied (c.p.m.)	
	H strands	L strands	Calf thymus (blank)	
Samples				
A, heated	209 (76%)	68 (24%)	2	884
B, heated	538 (67%)	278 (33%)	20	2,650
C, heated	790 (82%)	170 (18%)	10	2,907
Controls				
H strands	26 (4%)	467 (96%)	7	1,370
L strands	447 (88%)	61 (12%)	7	1,267

Early replicative intermediates labelled with α -³²P-dTMP were prepared by incubating Col E1 DNA (10 μ g ml⁻¹) and an extract of *E. coli* YSI cells (100 μ l) in the standard reaction mixture (300 μ l) containing α -³²P-dTTP (0.5 Ci mmol⁻¹ for samples A and B; 2 Ci mmol⁻¹ for sample C), 10% glycerol and 2 mM spermidine². A freshly prepared extract was used for preparation of samples A and B. An extract which had been frozen and thawed twice during storage for a week at -20°C was used to prepare sample C. The reaction mixture was incubated for 10 min (for sample A) or 45 min (for samples B and C) at 30°C. DNA was extracted and early replicative intermediates (26 S) were isolated by neutral sucrose density gradient centrifugation^{2,3}. A portion of these samples was heated at 90°C for 90 s to separate 6S fragments from the parental strands¹. Since the amount of contaminating labelled completely replicated molecules was negligible (Fig. 1a and ref. 2), the heated samples were used to hybridise to separate strands of Col E1 DNA without further purification. The two strands of Col E1 DNA that had been treated with endonuclease *EcoRI* and denatured were isolated by CsCl density gradient centrifugation in the presence of poly(U,G)⁶. Col E1 DNA labelled with ³H-thymine (1 mCi mmol⁻¹)⁴ or ³²P-H₂PO₄ (100 mCi mmol⁻¹)² was used to prepare the separate strands. ³H-labelled separate strands or denatured calf thymus DNA (0.3 μ g each) was fixed on a membrane filter⁷. Hybridisation experiments were carried out essentially as described⁷ except that three filters each of which was loaded with the H strands, L strands or calf thymus DNA were placed together in a hybridisation mixture (1 ml). After incubation for 18 h at 64°C, the filters were washed and radioactivity was measured. The ³²P-labelled separate strands were used to test cross contamination of ³H-labelled separate strands fixed on filters. The ³²P-labelled separate strands were purer than the ³H-labelled separate strands because the concentration of ³²P-labelled strands (0.01 μ g ml⁻¹) used in the centrifugation for strand separation was much less than that of ³H-labelled strands (2 μ g ml⁻¹) used. The values in parentheses are the fractions of labelled DNA which hybridised to separate strands in the total hybridised DNA (the blank value was subtracted). Based on the results in row 4 and 5, it may be argued that the fraction of 6S H DNA in the total 6S DNA may be slightly overestimated.

Fig. 3 Polarity of the strands of an early replicative intermediate (*EcoRI* cleaved) and the site of origin of replication.

Since most type I intermediates had a 6S L fragment and these molecules can complete replication, the site of initiation of replication of a 6S L fragment is the origin of replication of most of the molecules. The site is the 5' end of the fragment because DNA polymerase I, which extends a polydeoxyribonucleotide chain in the 5' to 3' direction⁸, is involved in the synthesis of the fragments (my manuscript in preparation). The polarity of a 6S L fragment can be deduced from that of Col E1 DNA strands, which was determined previously⁷. The 3' end of the H strand in the linear molecule created by cleavage of a closed-circular Col E1 DNA molecule by *EcoRI* is located closer to the region of early replication than the 5' end of the strand. The end of the linear molecule with the 3' end of the H strand corresponds to the left end of the molecule previously defined⁴. Therefore the 5' end of the 6S L fragment is located at the left branch point (approximately 17% of the molecular length from the *EcoRI* site^{2,4}) in the intermediate as illustrated in Fig. 3. It should be noted that unidirectional expansion of a replication loop, as was found in electron microscopic studies^{4,9,10}, does not mean that initiation of replication occurs from the fixed branch point since the method, in principle, does not reveal the site of initiation of replication and the direction of replication within the smallest replication loop observed.

Different mechanisms of initiation of synthesis of DNA strands on single-stranded phage DNAs have been reported. Initiation of synthesis of the complementary strand on M13 phage DNA is primed by *E. coli* RNA polymerase which presumably recognises a double-stranded region of the DNA¹¹. On the other hand, synthesis on ϕ X174 phage DNA and G4 phage DNA does not involve the RNA polymerase^{12,13}. In the replication of Col E1 DNA, initiation of synthesis of 6S L fragments in early replicative intermediates is completely blocked by rifampicin, while synthesis of 6S H fragments as well as further replication of the intermediates is not inhibited by rifampicin. Purified *E. coli* RNA polymerase can carry out a reaction that is equivalent to the rifampicin-sensitive reaction and is probably involved in synthesis of the primer for 6S L fragments (J. T. and T. Kakefuda, unpublished). Thus the mechanism of synthesis of the first fragment from a specific origin of replication is different from that of the fragments subsequently formed. Utilisation of the two distinct mechanisms may be advantageous by reducing the chance of aberrant initiation of replication of the molecule.

matters arising

Empirical formulae for Student's function

THE empirical formula devised by Dawson¹ for the calculation of the theoretical values of the Student's t function at any level of probability is a useful addition for many statistical programs. I have found that the following empirical formulae provide a simple method for calculating t at various defined probability levels, P :

$$P = 0.10; t = 1.64485 + 1/(0.648n - 0.534)$$

$$P = 0.05; t = 1.95996 + 1/(0.413n - 0.423)$$

$$P = 0.01; t = 2.57582 + 1/(0.193n - 0.273)$$

where n is the number of degrees of freedom. With three or more degrees of freedom these formulae give t accurate to 0.06%, 0.1% and 0.5%, respectively. A computer program using these formulae would require only the addition of the values of t for one and two degrees of freedom. These formulae are not only more accurate than Dawson's, but are also more suitable for hand calculators.

Cape diastrophism

IN a recent paper¹ on the Cape Fold Belt, the folded strata discussed range in age from late Ordovician² to late Permian³. Until the early Permian these strata were derived from the north^{4,5}. The ensuing palaeoslope reversal⁶ marks the lower limit of the Cape diastrophism, and transportation of sediment from the west and south can be related to the two fold trends subsequently developed⁷. Karroo dolerites are excluded from the fold belt, and their upper age limit⁸ defines the end of the diastrophism. From the Ordovician to the early Jurassic there are very real Gondwana links: for example, the Malvinokaffric fauna⁹, the distribution of the Permo-Carboniferous glaciation¹⁰, of *Mesosaurus*¹¹, and of *Lystrosaurus*¹². The diastrophism was terminated by major faulting, and earliest marine sediments¹³ occur in the mid-Jurassic. This was the forerunner of the spreading of the South Atlantic, which commenced at this latitude about 130 Myr ago¹⁴. Before that the Falkland Plateau

lay immediately south of the Agulhas Bank¹⁵.

de Beer and his coauthors proposed¹ that an oceanic plate underthrust Gondwanaland coincident with the present southern limit of Africa, and that the Cape Fold Belt resulted from an ensuing continent-continent collision directed from the south. The data given here cannot be reconciled with this suggestion for five reasons.

First, slow shelf subsidence characterised the area for almost 200 Myr before folding. Second, there are two fold trends, one parallel to the proposed direction of collision. Third, the Agulhas Bank is considered to be floored by similar material to that present onshore¹⁶, and presents no evidence of a major suture. Fourth, the impressive similarity of the Emsian faunas of South Africa and the Falkland Islands¹⁷ suggests that the position of the latter in Devonian times was the same as in the Jurassic. Finally the concept of a plate underthrusting Gondwanaland from the south implies that Gondwanic continents such as South America and Antarctica were not in the pre-Mesozoic positions commonly ascribed to them and consequently, that the collision would involve a continent lacking Gondwana affinities. However the Cape diastrophism may have formed, a plate tectonic model is not well served by failure to consider such material evidence.

DE BEER ET AL. REPLY—Truswell's comments¹ deal mostly with matters outside the scope of our original letter², which was intended to consider geophysical anomalies near the Cape Fold Belt and, if possible, to relate these to proposed geological models. We agree that the model suggested in the paper is simplistic and could be misinterpreted.

Although the folded strata range in age from Upper Ordovician³ to Upper Permian⁴, the main phase of folding was in the Triassic⁴. The less severe, north-south trending Cedarberg folding occurred in pre-Dwyka times⁴. The first signs of a southern land mass⁵ and pre-Dwyka folding in the east-west trending fold belt⁴ are observable in Witteberg (Lower Carboniferous) strata. This southern land mass was not simply an uplifted part of the continental craton, but an island arc type of orogenic belt, possibly related to a subduction zone south of the present coastline^{6,7}.

An important point is that the Cape Fold Belt represents only the northern edge of the more extensive Samfrau geosyncline of Gondwanaland^{8,9}. The orogenic belt and igneous rocks related to the inferred subduction zone are thus not in South Africa but lie in Patagonia and western Antarctica^{7,9,10}.

Truswell's objections to our model can be covered point by point.

First, the folding in the southern Cape occurred during Lower Carboniferous times, which means that shelf subsidence lasted only about 100 Myr before the start of any orogenesis related to subduction. Second, the degree and type of deformation accompanying continental collision (or continent-island arc collision) depend on the shapes of the continents and the morphology of the trench system, or systems, involved (see, for example, ref. 11). A fold system with only two fold trends of different ages will require a relatively simple model. The relevant geological and geophysical evidence from South America and Antarctica must be included in such a model. Third, this indicates that the

suture will be further south. Fourth, geophysical evidence strongly suggests an Upper Triassic–Lower Jurassic Gondwana model in which the Falkland Plateau as part of the South American plate borders the African plate^{12–14}. This model is consistent with Truswell's considerations and with the hypothesis that the Falkland islands were to the north of the inferred subduction zone. The position of the subduction zone with respect to Patagonia is unclear. If it was situated to the east of Patagonia, the suture could lie in the basement structures in the continental edge and in the Malvinas Basin¹⁵. The suture could then cross the continent in the Upper Permian Patagonian Massif⁸ or the Middle Triassic Desado Massif¹⁶. Geological evidence, however, strongly supports the existence of a subduction zone that bordered the western rim of Patagonia from Devonian to Triassic times^{7,17}.

Fifth, from the Gondwana model it is clear that parts of Patagonia and the Antarctic Peninsula formed the southern land mass that approached southern Africa during Palaeozoic times in a process peripheral to the main Gondwana land mass. Even this accreted land mass should show affinities with Gondwanaland from at least Lower Carboniferous times.

This first order extension of our very elementary model inferring a continental collision origin for the Cape Fold Belt shows that the constraints proposed by Truswell can indeed be reconciled with a continent–continent (or at least a continent–island arc) collision south of Africa.

Our explanation of the origin of the Beattie magnetic anomalies is more contentious and should perhaps be related to processes causing the accretion of the present-day basement in the Karroo and further south rather than to processes causing the formation of the fold belt.

Chocolate, β -phenethylamine and migraine re-examined

ON the basis of an industrial analytical report indicating that chocolate might contain as much as 3 mg of β -phenethylamine (PEA) per 2-ounce bar, Sandler *et al.*¹ administered 3 mg of this amine to each of 36 chocolate-sensitive migraine-prone subjects and found that 18 suffered attacks within 12 h, as opposed to six attacks with placebo.

zene-ethyl acetate (9:1). A portion of the eluted radioactive zone was counted and a smaller portion was injected on to a column containing 3% Poly A-103 on Gas Chrom Q (F and M Model 400, fitted with Hewlett-Packard ⁶³Ni electron capture detector). With the use of external standards prepared from crystalline N-heptafluorobutyryl-PEA and an estimate of losses provided by recovered ¹⁴C, a simple calculation provided the native PEA level.

As Table 1 shows, the highest level, 780 μ g per 2 ounce, was found in the unsweetened variety. Semi-sweet forms contained intermediate amounts and milk chocolate was lowest in PEA. The decline may be related to the amount of time the raw chocolate is subjected to conching, a mellowing process during manufacture which includes rolling and heating. PEA, a relatively volatile amine, could escape during this step. The modest rise in PEA after relatively severe hydrolysis indicates that presumed conjugates do not contribute substantially to the total potential PEA pool.

Table 1 PEA levels in various brands of chocolate

Brand	Country	Type*	μ g PEA-HCl per 2 ounce		Recovery of PEA-HCl added to 1 g chocolate		
			First analysis	Second analysis	Added (μ g)	Native level (μ g)	Total recovered (μ g)
A	England	Milk	38	41	—	—	—
B	USA	Mild sweet	285	315	1.0	5.0	6.2
		Milk	78	85	50.0	1.4	57.0
C	USA	Mildly sweet	330	—	—	—	—
		Milk	21	—	—	—	—
D	USA	Semi-sweet	360	390	1.0	6.4	8.2
		Unsweetened	780	978†	20.0	13.8	35.7
E	Switzerland	Milk	86	—	—	—	—
		Bittersweet	260	—	—	—	—
F	Switzerland	Milk	103	—	—	—	—
		Bittersweet	340	—	—	—	—

*Manufacturer's description.

†Sample subjected to 100 °C hydrolysis in 6 M HCl for 0.5 h.

Having previously developed a sensitive procedure for the analysis of PEA in urine², we applied it with minor modifications to the analysis of one US brand of milk chocolate. We found only 21 μ g per 2-ounce bar, or about 1/150 of that quoted above. Various brands and types of chocolate were then examined.

In the method, 1-¹⁴CPEA, 8.86 mCi mmol⁻¹, was used as an internal standard. About 10⁵ d.p.m. were added to 1–2 g chocolate melted in 5 ml water. With some samples, 1–50 μ g of unlabelled PEA was also added in tests to demonstrate recovery. Briefly (see ref. 2 for details), bases were extracted with chloroform. After concentration, the residue was applied to a silica gel plate and developed in ethylacetate–methanol–diethylamine (9:1:1). The labelled area, eluted and derivatised with heptafluorobutyric anhydride, was chromatographed in ben-

These data suggest that chocolate-induced migrainous attacks are either not related to PEA-induced headaches, or that patients suffering from migraine are sensitive to very low levels of PEA.

This work was supported by a Research Scientist Award to A.J.F. and a grant from the National Institute of Mental Health.

Cell Biology, 6/e

By E. D. P. DeRobertis, MD, *University of Buenos Aires, Argentina*
Francisco A. Saez, PhD, *Montevideo, Uruguay*,
and E. M. F. DeRobertis, Jnr., MD, PhD, *University of Buenos Aires*.

Revised and up-dated, this sixth edition retains its wide coverage of such subjects as cell structure and ultrastructure; biochemistry and molecular biology; and techniques for optical and chemical analysis. The discussions of enzyme kinetics (including allosteric interactions), protein synthesis, and muscle and cell division have all been radically changed.

reviews

THE first volume of this textbook, dealing with the principles of the subject, appeared in 1962 and reached a second edition in 1968. Good of its kind, it necessarily follows fairly conventional lines. The second volume aims at global history in a way that has never previously been attempted. It was about three-quarters complete when H. H. Read died in 1970, in his 80th year; Professor Janet Watson is to be congratulated on bringing the eagerly-awaited work to fruition.

The method adopted is to integrate the broad record of stratigraphy of rocks formed at or near the Earth's surface with structural, magmatic and metamorphic events which occurred at depth within the crust. The evidence comes fundamentally from geological mapping at the surface, with data on the third dimensions derived from valleys, mines, boreholes and the indirect probing of geophysics. The process has been carried to a very variable degree in different parts of the world, but there is no doubt that the time is ripe for synthesis on the scale attempted here. Moreover, the classical method of time-assessment from fossils has now been carried far back into the Cryptozoic, and the newer method of radiometric dating gives a valuable control over Cryptozoic and Phanerozoic alike, once its limitations have been appreciated. The authors point out, however, that they have had to place severe limitations upon the amount of stratigraphic (and, therefore, palaeontological) detail given. The framework is, in fact, not stratigraphy but tectonics and this follows very suitably from the last chapter of Volume 1 ("A pattern of earth history") which drew a sharp distinction between stable regions of the crust and belts of mobility. The history of the

New geological framework

Introduction to Geology. Vol. 2: Earth History. By H. H. Read and Janet Watson. Part 1: *Early Stages of Earth History*. Pp. xii+221. £5.95 board; £2.95 paper. Part 2: *Later Stages of Earth History*. Pp. xii+371. £6.95 board; £3.95 paper. (Macmillan: London and Basingstoke; distributed in the USA by Halsted Press; May 1975.)

mobile belts is adopted as the framework for Volume 2, though the cratons of Precambrian time, the interior lowlands, epicontinental basins and forelands are by no means forgotten.

Volume 2 is issued in two parts in order to make possible the publication of the paperback edition. Part I deals with the first 2.9×10^9 years, covering Precambrian events up to the later Proterozoic. As far as I know, this is the first time that a global synthesis of the Precambrian, involving all the continents including Antarctica has been attempted. For each continent, an outline of the tectonic pattern is first given; then the stages by which the rocks older than 900 Myr have been formed is set forth. A concept of a series of cycles emerges; the ending of a cycle brings stability to tracts that were formerly mobile, contributing to the growth of cratons; but the initiation of a new cycle may affect tracts that were formerly stable.

Many interesting problems for future solution come directly from this synthesis.

Though it seems unlikely that a stratigraphic classification like that adopted throughout the world for the Phanerozoic will ever become feasible for the ancient rocks, some correlations certainly begin to emerge, as Figure 10.1 shows in the book. Indeed Part I will make good reading for those involved in the Precambrian priority area of the International Geological Correlation Programme of UNESCO/IUGS.

Part II commences with a chapter on new themes in Earth history which provides a convenient way of dealing with continental drift and palaeoclimatic change. The method used in Part I is then readopted and the framework again established on mobile belts, but belts which will be much more familiar to most readers than those described in Part I: the Caledonian, Hercynian-Uralide, Alpine-Himalayan and Cordilleran. The interior platforms of little distorted cover-rocks resting on Precambrian or later basement receive due attention, and the break up of the great ancient southern continent of Gondwanaland is described. This leads on to the current concepts of global tectonics, the opening of the Atlantic and Indian oceans, and the outward circumferential push around the Pacific.

Even if the authors have had to scale down the over abundant geological detail, they have succeeded in following those aspects of geological process that can be traced throughout the full span of Earth history, at the same time pointing a finger at a few, like banded ironstone formation or the detrital transport of uraninite, that long ago ceased for ever. Surprisingly in this historical essay, the useful rocks and minerals are not forgotten, but appear in their due genetic positions.

Kingsley Dunham

TRANSPORT of peptides across biological membranes, first discovered in microorganisms, is now recognised to be of major significance in the intestinal absorption of amino-N, yet little is known of other roles of peptide transport.

The variety of peptides— $20^2=400$ dipeptides alone—and the range of their biological activities is astonishing. Some are hormones, others vasoactive. There are peptides called 'smugglers' that carry otherwise impermeant molecules piggyback across membranes. Peptides contribute sig-

Peptide transport

Peptide Transport in Protein Nutrition. (North-Holland Research Monographs, Frontiers of Biology, Volume 37.) Edited by D. M. Matthews and J. W. Payne. Pp. xxii+503. (North-Holland: Amsterdam and Oxford; American Elsevier: New York, 1975.) Dfl. 130; \$54.25.

nificantly to the flavour of foodstuffs. Some taste extremely sweet, others containing acidic and neutral amino

acids taste sour but (see page 55) Mrs Beeton's recipe for tasty beef tea produces a satisfactory mixture.

The Editors and their eight colleagues have succeeded in delving into diverse disciplines to produce a generally well-balanced account of knowledge of peptides, with the emphasis on nutrition.

This is an expensive book (10 pages = \$1.00), but an essential acquisition for libraries. It will be read with profit by biochemists, clinicians, nutritional scientists and food technologists.

Dennis Parsons

Guide to the Marine Stations of the North Atlantic and European Waters. Part I. Northern Europe and the East Atlantic Coast. Compiled by J. E. Webb. Pp. 263+34 figs. (The Royal Society; London, 1974.) £2.50 (UK); £2.60 (overseas).

THIS guide, compiled by Professor J. E. Webb, is the first of a new series of handbooks which will be extended in further parts to cover marine stations of the Mediterranean, the Atlantic seaboard of USA and Canada, and the Caribbean and Gulf of Mexico.

Part I is an invaluable source of information on the facilities offered at 33 European marine stations, including 12 within the United Kingdom and Eire. The information is concise and practical. Short descriptions are given of the main types of shores to be found in the neighbourhood of the stations; of the common animals that can be obtained without difficulty; at the time of year when they occur; of the ships, boats and vehicles that are available for field surveys; and of the types of gear at hand for the collection of specimens and data.

The number and nature of the services provided in the research rooms and laboratories of the station are listed. The availability of special apparatus, such as is often required by physiologists, is briefly but usefully noted; and an intending visitor may be guided on the nature of the apparatus, equipment and materials which a station may be able to provide. Notes on the voltage, d.c./a.c. frequency, and phase of the electricity supply at the various stations are especially useful. Excellent outline maps showing the locations, the nature of the shorelines and the approaches to stations, illustrate the guide.

The guide, as noted in the preface, is not intended to be comprehensive. Some additional information would perhaps have been useful, such as the languages commonly spoken, the technical assistance that a visitor might expect to receive and fuller notes on the characteristics of the plankton and algae. The guide is, however, in a form which lends itself to ready revision as the need arises, and in its present form it is up-to-date and informative. **J. E. Smith**

Comprehensive Virology. Edited by Heinz Fraenkel-Conrat and Robert E. Wagner. Vol. 2: Reproduction—Small and Intermediate RNA Viruses. Pp. xiv+340. \$33.60. Vol. 3: Reproduction—DNA Animal Viruses. Pp. xiv+488. \$38.50. Vol. 4: Reproduction—Large RNA Viruses. Pp. xii+347. \$34.90. (Plenum: New York and London, 1974-75.)

VOLUME I of *Comprehensive Virology* was essentially a catalogue, containing a very limited amount of descriptive material. The next four volumes, of which volumes 2, 3 and 4 are now published, are entirely different from Volume 1, and are all concerned with the ways in which viruses reproduce themselves. These are major reviews, and although one or two contributions show signs of being variations upon earlier texts by the same author(s), much of the work is new and up to date. The sections in Volume 2 by E. R. Pfefferkorn and D. Shapiro on togaviruses, and in Volume 3 by B. Roizman and D. Furlong on herpesviruses, are particularly fresh and original. Later volumes will deal with structure and assembly, and with regulation and genetics. This approach means that a virologist with an interest in one particular virus family is obliged to buy three volumes in order to cover all aspects of his particular virus. By so doing, however, he is likely to read more widely than if he confined himself to single-virus books on 'poxviruses' or 'herpesviruses', and will thus benefit himself as well as the publishers. **J. S. Porterfield**

Books brief

Introduction to Geochemistry. (Geophysics and Astrophysics Monographs, vol 10.) By Claude-Jean Allègre and Gil Michard. Pp. viii+142. (Reidel: Dordrecht and Boston, Massachusetts, 1974) n.p.

Handbook of Geochemistry, vol. 2, part 4. Edited by K. H. Wedepohl. Pp. vi+898. (Springer: Berlin and New York, 1974.) DM.298; \$122.20.

WERE he to judge from the title the tyro might expect *Introduction to Geochemistry* to provide a comprehensive appraisal of geochemistry at a reasonably elementary level. Instead, he will find a good introduction to certain important geochemical processes. The book confines itself essentially to element fractionation: the fractionation of major and trace elements through magmatic processes and in the hydrosphere; the fractionation of light isotopes, with particular reference to $^{18}\text{O}/^{16}\text{O}$ and $^{32}\text{S}/^{34}\text{S}$ isotopic compositions; and of radioactive isotopes. Natural processes in which chemical equilibrium is not attained are also considered.

The book is a translation, "done without amendments, editings or alterations", and, consequently, it appears as a translation, although the

sentence, 'A test of the validity of these equations can be gotten here in a simple way' conjures up some thoughts about the original French. The authors' "rule" to omit many text citations from the bibliographies is irritating.

The *Handbook of Geochemistry*, the latest part of a continuing project, upholds its high standard of content and production, and meets its publication date. The authors, editors and publishers are all to be congratulated on maintaining the impetus of the project. Chapters covering a further 24 elements (including carbon, nitrogen, oxygen, silicon, magnesium and iron) are now supplied; little is missing from another 21 chapters; and with more than three quarters of the elements completed only relatively small gaps remain. Inevitably, with publication over a six-year period, costs have escalated, but at least fairly uniformly. The price is now 14.7 cents for each page, compared with a price of 5.5 cents in 1969. The *Handbook of Geochemistry* is invaluable to earth scientists, but regrettably, it is a library purchase, and these days even some libraries may resist temptation. **Duncan Murchison**

Fast Reactions. (Oxford Chemistry Series.) By J. N. Bradley. Oxford Chemistry Series (Number 23). Pp. x+121. (Clarendon: Oxford; Oxford University Press: London, June 1975.) £3.25.

PROFESSOR Bradley has written a very concise description of fast reaction kinetic studies, emphasising throughout his book the experimental rather than the chemical aspects of the subject. The descriptions of the individual techniques are not very detailed, and the author's own interest in gaseous, rather than solution work, is very apparent. A preferable presentation would have been to split the subject into two parts of this series, one referring to gaseous the other to solution kinetics. In any case the value of the book would be greatly enhanced by the provision of many more up-to-date chemical examples, particularly for the solution kinetic techniques. The standard of production of the book does not compare favourably with others in the series: the print was blurred on many of the pages of the reviewer's copy, and the line lengths had not been justified. A number of diagrams need better description or more labelling, and there are a few text errors. The reviewer will continue to use Caldin's *Fast Reactions in Solution* (1964) and Hague's *Fast Reactions* (1971) as preferred recommended texts.

John Maher

Bonded states

Metal-to-Metal Bonded States of the Main Group Elements. By M. J. Taylor. Pp. 211. (Academic: New York and London, May 1975.) \$15.25; £5.80.

COMPOUNDS in which ligands are linked to a cluster of atoms, instead of to a single atom, have opened up much novel chemistry in recent years. Much of this has been in transition metal chemistry, but cluster compounds spread right across the periodic table, and interest in them stems from their novel compositions, the apparently low valence states of the elements, their stereochemistry and their valence-theoretical description.

Dr Taylor has explicitly restricted himself to compounds of the main group elements. In addition, he limits consideration to compounds of elements that, in the elementary state are regarded as metals. There is no real justification for doing so, and the arbitrary restriction has some illogical consequences. Thus, he has to discuss the cationic clusters formed by selenium and tellurium without proper reference to their exact analogues in sulphur chemistry, and he makes no mention at all of the anionic clusters formed by silicon and germanium. But equally mistakenly in my opinion he broadens his survey to include all compounds in which two 'metal' atoms are linked. The real interest of metal-metal bonding surely resides in the consequence of electron delocalisation within a cluster or chain of identical (or at least essentially interchangeable) atoms. The pro-

perties of, for example, the $(\text{CH}_3)_3\text{Sn}$ group, like those of the $(\text{CH}_3)_3\text{Si}$ or even the $(\text{CH}_3)_3\text{C}$ group, are those of a straightforward σ -bonding group; there is nothing special about such compounds as $(\text{CH}_3)_3\text{SnCo}(\text{Co})_4$, or $(\text{CH}_3)_6\text{Sn}_2$, to justify special attention to the 'metal-metal' bond. The amount of space devoted to compounds of this kind dilutes what should be the main interest of the book.

What the book does provide is much information on the formation of dimer and cluster species, in solutions and melts, and structural information based on vibrational spectroscopy and crystal structure. It has a thorough bibliography, heavily biased towards work of the last 15 years, including references up to 1973. This review content is its main value. For student reading, it does not bring a unifying outlook to a diverse field; for example, there is repeated terminological confusion between the oxidation states, which may often be experimentally determined, and the valence states of elements which in cluster compounds are certainly different from the oxidation states and which may be debatable. There are many typographical errors, but few will lead to confusion. Readers will note that, on the dust jacket, Academic Press have now decreed that selenium and tellurium shall be Group Vb elements.

The author states that the book is an expanded treatment of a review. One must query whether that expansion was really justified. A good review does not necessarily produce an equally good monograph. **J. S. Anderson**

Literature on water

Water and Aqueous Solutions: Introduction to a Molecular Theory. By Arieh Ben-Naim. Pp. xvi+474. (Plenum: New York and London, 1974.) \$34.90.

THE basic thesis of this book is that some sort of mixture model provides a fundamentally correct physical description of the thermodynamic properties of water and aqueous solutions and that mixture models can be made respectable or rigorous by embedding them in or deriving them from the fundamental statistical mechanical theory of fluids. The author is not particularly concerned with establishing the validity of any particular mixture model. Rather, he is concerned with the features common to all such models and with giving precise statistical mechanical definitions of the concepts used in discussing them.

The first half of the book discusses the statistical mechanics of fluids, molecular distribution functions, and the theory of solutions. The last half is concerned with liquid water, water with one simple (non-hydrogen-bonding) solute, and

water with two simple solutes. The emphasis in this second half is almost entirely on thermodynamic properties, rather than on time dependent or spectroscopic measurements. A major limitation of the book (which is a reflection of when its writing was completed) is that it contains only a brief discussion of the earliest computer simulation studies of realistic models of water. Such studies should provide the most convincing evidence for or against the usefulness of mixture models.

Many of the features of the book are of interest and of value even to the reader who does not share the author's preference for mixture models; for example, the careful discussion of those aspects of solution theory which are needed to understand experiments on aqueous solutions, the precise discussion of standard thermodynamic quantities of transfer, and a statistical mechanical definition of the concept of hydrophobic interaction. Though the book does not answer many questions it does formulate many about water and aqueous solutions in a precise way. It is a useful companion volume for the large recent review literature on water. **Hans C. Andersen**

HYDRODYNAMIC FLUCTUATIONS, BROKEN SYMMETRY, AND CORRELATION FUNCTIONS

Dieter Forster

Presents the theory of fluctuations and linear response in many-body systems and their description in terms of response functions. The emphasis is to formulate the theory in a simple and unified fashion to allow the reader to appreciate and exploit the many analogies which exist between, for example, superfluids and liquid crystals. The level of the text is deliberately held very simple. It will be easily accessible to physics and chemistry students in their first or second year of graduate school, particularly because the emphasis is on the physical principles rather than on mathematical completeness and detail.

Why industry and academics go their separate ways

ACADEMIC engineers say that industry

- has not the imagination to see long term potential;
- is unreliable when it comes to financial, and even moral, obligations;
- shows little interest even in projects it has backed itself;
- reacts to proposals through its accountants;
- wastes highly qualified manpower;
- is too secretive about its policies and the results of research projects.

For good measure, industry says that academics

- cannot keep to deadlines;
- get distracted from central objectives of projects;
- have too many other responsibilities to manage a project properly;
- are not keen to work to specific contract with a time scale;
- are insensitive to the realities of the market place;
- promise more than they can provide;
- have little notion of the human and environmental contexts of technology.

The caricatures described above do not come from a confidential telephone number to which malcontents could express their anonymous gripes; rather they come from a Science Research Council report published last week and entitled *Academic-Industrial Collaboration in Engineering Research* (SRC, free of charge). We hasten to add that the SRC is not urging these opinions on the community—it is simply reporting, through a panel headed by Professor E. J. Richards (Loughborough University), the common stereotyped views that still circulate widely and undoubtedly have some substance.

The panel, like many predecessors, is concerned at the “far from satisfactory” links between university and industry, and particularly links which develop, or fail to develop, when universities look to the SRC for support in engineering research ventures which are too speculative and risky for industry to pursue in its own laboratories. The problem is put more simply and chauvinistically by politicians and newspapers—“Why do we have so many good ideas and then waste them or let a foreign company exploit them?”

This popular viewpoint may be quite wrong. British companies may steer clear of certain ideas with justification. The panel acknowledges that in some industries (computers, for instance) the collaboration is much easier to bring about. And in some cases the international nature of corporations makes simple-minded talk about British universities benefitting British industry dated and meaningless. But there is no denying that there is still much uneasiness that universities and industry go their separate, mutually incomprehending ways far too much.

The panel sees three serious gaps in the present framework for research support:

- A pre-development gap between researcher and industrialist concerning the time at which a research project can be seen to have an outcome. The academic scents success for an idea long before an industrialist is convinced; the panel urges that bridging work be given much greater support, by either the SRC, the universities, industry or research associations. This is the central message for SRC who have traditionally only supported research.
- An evaluation gap between researchers and industrialists in the following-through of research results. The panel points an accusing finger at the SRC whose record is “very poor” in the dissemination of information so that industry can get early warning of developments.
- An identification gap; it seems that academics would positively welcome a more interventionist approach by the SRC in policy formation and implementation. There is much, says the panel, that the Engineering Board (of the SRC) could do to improve its own ability to identify research needs.

It is striking how much of what the panel says boils down to one problem—adequate communications. Perhaps the most telling section of the report runs: “... success [in collaboration] depends strongly on the compatibility of the individuals in contact, and their enthusiasm for the project. Clearly defined objectives and responsibilities are also important, but rank second to satisfactory human relationships”.

The panel was in no position to do more than make recommendations relevant to the SRC’s policy, but it seems abundantly clear that at some time two broader issues will have to be faced.

First, are not engineering departments in many universities too isolated? The separation of university entrants into mathematicians, scientists, and engineers, each pursuing separate educational paths (and sometimes attending almost identical lectures) not only makes it more difficult for the student to sample widely and choose appropriately but also encourages an artificial erection of barriers around engineering which is bound to lower the general ability to communicate.

Second, the amount of movement in mid-career between university and industry, either for a year or for an indefinite period, is still pitifully small. It is certainly possible to point to short term exchanges, but if communication is to be improved it must be on the basis of understanding the constraints under which the ‘other side’ works. This can hardly be done in a few weeks, but rather requires people to stay long enough not just to be involved in the making of decisions, but also to have to live with the consequences of those decisions. □

The International Institute of Cellular and Molecular Pathology (above) was inaugurated as a centre for medical research last April. Christian de Duve (below) is president of its governing body as well as chairman of the executive committee and in those capacities he directs the activities of the ICMP. The institute is already acting as a honey-pot for expatriate Belgian scientists but it is de Duve's problem to try and make the institute live up to its 'International' intent. Peter Newmark reports from Brussels.

THE ICMP will probably be international before it is truly national, having been born out of the long standing Belgian failure to integrate the French and Flemish-speaking communities. Separatist movements at the Université Catholique de Louvain (UCL) triggered off such disruptions in 1968 that co-existence on one campus became impossible. It was during the ensuing upheaval that the idea of the ICMP arose, along with a government plan to found a separate French-speaking UCL on Walloon territory. The outcome of subsequent deliberations was a brand new campus in a Brussels suburb. On this campus are sited a 900-bed hospital, the new UCL medical school and the ICMP.

In spite of the very close links between the ICMP and the medical school, including the fact that all the senior members of the former hold chairs at the UCL, the institute aspires to autonomy, and is well on the way to it. Thus it is registered as an independent body, has its own charter and governing body and maintains a Scientific Advisory Board of international notables who are consulted before any important appointments are made. (Advice in the negative from them has already been followed on occasion.) In addition the official language of the ICMP is English.

All research at the ICMP is intended to be medically orientated but with

some categorisation into basic and applied projects. The organisation is described, perhaps more for the benefit of laymen and fund-raising than for experienced scientists, as consisting of a central core of basic scientists on to which are attached groups that are tackling more applied problems—the promised advantage being that many diverse groups can obtain adequate basic support from the multiple skills of the core.

So far the majority of the staff, at present numbering about 150 including supporting personnel, belong to the 'central core'. They divide into four main groups. Largest by far is de Duve's biochemistry group which concentrates its work on subcellular particles and the metabolism of both glycogen (under H. G. Hers) and connective tissue (under G. Vaes). The experimental medicine group is the next largest. Led by J. F. Heremans, it provides the immunological know-how of the ICMP and has an active interest in various proteins of body fluids. Third, there is a general pathology group operating in the field of endocrinology, particularly thyroid hormones, under M. de Visscher. And finally there is C. Cocito's small microbiology and molecular genetics group. Each of these four groups was located separately until the ICMP united them and each is very enthusiastic about its new brotherhood.

But what of the new groups that de Duve is hoping to graft in to, or preferably on to, the existing 'central core'? So far a large grant from a French drug company has enabled A. Trouet to set up an experimental chemotherapy unit, T. Boon is about to join the institute to start up a cellular genetics group that will concentrate on teratocarcinomas and there are advanced plans for a parasitology group backed by the WHO.

Noticeable at this stage largely for their absence are any new clinically orientated research groups. Since these are part not only of the design but also of the justification of the ICP, they will have to be started in due course. The main question that concerns de Duve at present is whether he can find suitable staff to originate and run new groups.

In his favour are the fine facilities of the ICP, the permanent posts that can be offered and the fact that de Duve (no band-waggoner himself) is prepared to back almost any line of medical research provided he finds the right person. Against him is the considerable problem of attracting the foreign candidates that de Duve is after.

Why look for foreigners? In the first place there simply are not enough top-class Belgian scientists: second, there is the 'International' label to live up to. But over and above those reasons is de Duve's profound belief in the value of mobility among scientists. This belief is nurtured by de Duve's long association with the Rockefeller Institute where he spends about half his time and will continue to do so. In fact, the Rockefeller clearly plays a godparent role to the ICP, acting as a general model, having been a temporary home for most of the senior staff at one time or another and providing two of the members of the Scientific Advisory Board.

Also in line with de Duve's encouragement of mobility will be his policy of only giving tenured posts to the most senior of newly appointed staff. Others will be taken on limited appointments of a few years, some on a fellowship programme that is about to start.

It remains to be seen how successful this policy will be at a time when even the best young scientists are not prepared to take untenured posts except as a last resort.

Professor de Duve is a modest man, courageous enough to try and build up an international institute in a city which, apart from becoming the Washington of the European Economic Community, has few outstanding attractions. His Nobel Prize last year has not only brought him fame and fortune but has been an exceptionally timely boost for the ICP. □

THOMAS JUKES

Evolutionists brought to book

THIS year is the fiftieth anniversary of the "Scopes Trial" in Dayton, Tennessee, when the issue of teaching evolution was argued between William Jennings Bryan and Clarence Darrow. The trial was showbiz, not, as some have thought, a public martyrdom of Scopes. It was put "on the air" in one of the first coast-to-coast network radio broadcasts. Scopes was fined \$100, this was paid by the *Baltimore Sun*, and Scopes left Tennessee to accept a graduate fellowship (a rarity in those days!) offered because of his new fame. The evolutionists got their story to the public. At the time, it seemed that Bryan succeeded in convicting the defendant but that Darrow triumphed ideologically. Half a century later, the story of the trial, as told by H. L. Mencken, sounds archaic to the young, and nostalgic to their parents.

But there is an uneasy feeling that, as far as school textbooks in the USA are concerned, evolutionists may have won the battle of Dayton, but not the war. For publishers live by selling books, and it is poor for business when parents object to a science textbook: the competition would gladly omit "controversial material" to win the contract. As an "evaluator" for the California State Textbook Commission, I was prepared to resist the opponents of evolution on the State Board of Education. I found, however, that there was very little mention of evolution in the books. Publishers will not prepare a special "California edition", so the result is that the national versions have little to say about the subject, with the notable exception which Professor G. G. Simpson has noted, of those published by Harcourt Brace Jovanovich. □

The "textbooks" published by the Creation Science Research Center of San Diego have plenty to say, however. Much of their content is artfully directed towards attempts to discredit geological findings and isotopic dating. Few physicists, palaeontologists and geologists wish to get into arguments emanating from those who truly believe in a special creation that took place instantaneously 6,000 years ago. But I think we may learn a simplified approach from the following famous exchange in the Scopes trial:

DARROW: Mr Bryan, do you believe that the first woman was Eve?

BRYAN: Yes.

DARROW: Do you believe that she was literally made out of Adam's rib?

BRYAN: I do.

DARROW: Did you ever discover where Cain got his wife?

BRYAN: No sir; I leave the agnostics to hunt for her.

Fifty years later, creationists are passing the hat for the latest of their expeditions to look for the remains of Noah's Ark on Mount Ararat. Surely if they wish to argue about geology, we are entitled to ask a few questions about the Ark, its dimensions, and the time schedule of the Flood. These are set forth with great precision in the Book of Genesis, in an account which also contains one of the most cherished of allegories—that of the dove of peace.

Our creationist friends, literal and unimaginative, are more concerned with looking for pieces of wood. Very well. Let us ask them a few questions about ecology in its most compact form—the living quarters on the Ark for all terrestrial species (including koala bears, *Plasmodia*, tapeworms and tigers), plus their food supply and maintenance for 400 days, in a volume of 44 000 m³. There is also the minor question of what happened to about 1.6 × 10⁹ km³ of water when the flood receded. This much water would be needed to cover the Earth to a depth of 3,000 m, an increase in water level that would be actually only about half that required to submerge and drown "every living substance . . . which was upon the face of the ground."

But I digress. In some religious sects, there is still a zealous opposition to teaching evolution, and the effects of this have been recently visible in the states of California, Texas and Washington. The subject of evolution is one of our great cultural heritages, which has now expanded to encompass biology in a single network of molecules, and the recent problems in the USA are a lesson to all of us to keep up-to-date on knowledge of the fossil record and the methods of isotopic dating of rocks. □

ASTRONOMY, cradled in superstition, and fed in infancy by the fears of kings, only became a science when it dissociated itself from astrology and restricted itself to matters capable of mechanistic interpretation. Other sciences, including most fields of medicine, have likewise weaned themselves from their infant diets of credulity and crude utility. In consequence, chemistry, mathematics and physics have become reputable disciplines whose general scope and aim could not be misrepresented in public documents without exciting wide comment.

Why is the genetics of man not accorded the standards of public scrutiny and stock-taking normally afforded to radioastronomy, high-energy physics, and the genetics of flies? It can hardly be mere difficulty, for the basic mechanisms of genetics are, in principle, far simpler than those invoked for stars and atoms, and the genetics of man is only marginally more remarkable than that of the fly. Until we can diagnose the cause of this contagious mediocrity we cannot expect any cure, and without some attempt at cure we cannot expect that workers of the calibre expected in those who listen to the skies, or look for portents in bubble chambers, will be attracted to this field. The reputed mediocrity of physicians, a belief widespread among those who are not physicians, is hardly a reason, for immunology, virology, and numerous other specialised fields in and around medicine are progressing well.

The reason must be in ourselves. While we can accept, after many generations, the peripheral isolation of the Earth, and even the Sun, the full implications of evolution and of natural variability are too much. Genetic disorders are rare, and only a minority are amenable to elimination, to prevention, or to treatment. They have been with us throughout our evolution, and most are likely to stay with us for as long. They require the same basic facilities for research, for diagnosis, for treatment, and even for elimination, as do other forms of disease.

Genetic disorders are, by definition, those to which the flesh is heir, and cover all disease. In practice it is convenient to use the word 'genetic' to cover those disorders consequent upon some hereditary unit, or pair of units, which is usually either sufficient, or necessary, for the manifestation of disease, as in the genic and chromosomal disorders. Victims include those who, by chance, were conceived without the alleles necessary for synthesising pigment in the eye and skin, or, by mischance, were conceived with the handicap of an extra chromosome.

Even here words can be confusing,

for albinos rarely have inherited any noticeable disorder from their ancestors, and those burdened by an extra chromosome are usually born to parents with a regular allocation. But the term genetic, implying an inborn qualitative or quantitative abnormality in their nuclear apparatus which is sufficient to cause distress, is useful and rarely ambiguous. Obviously, the environment will influence affliction, but, within any regular environment, any inability to cope with minor injury, sunlight, or conventional food can be a sufficient handicap to qualify for the term 'disease'.

Genetic facts?

Once the word genetic is extended to cover any inborn predisposition, whether to illness, to aptitude, or to crime, difficulties arise which can only be removed by a less casual use of words. A recent publication from the US National Institute of General Medical Sciences, National Institutes of Health, (*What are the facts about genetic disease?*, with the strange subtitle, *Most ubiquitous of all human maladies*) does nothing to lighten the genetic load of confusion, and its authors have done a serious disservice to those—many of whom are featured in photographs in this booklet—who are striving for an orderly application of genetic knowledge to man.

The book tell us (p. 6) that 15 million Americans have birth defects, and that 80% of these "carry true genetic diseases due wholly or partly to defective genes or chromosomes". The genetic load is then elaborated to cover 100,000 abortions and 40% of infant deaths; each of us (presumably US citizens) carries "between five and eight recessive genes for serious genetic effects" and each married couple has a 3% risk of having a genetically defective child. The opposite page is a little less exact with recessives, giving the range as "between one and ten", and shows some normal looking individuals and a superimposed pedigree of the extremely rare and variable Hartnup disease, stating that the normal siblings are at risk of transmitting it to their offspring—a risk too low to justify anxiety, or even the use of the word risk.

Next, disorders of infancy are shown to cause more lost years of life than disorders of the aged. Single gene defects are said to occur in 1.8 to 2% of all births. But the "overall incidence of recognised genetic diseases is 4.8 to 5.0% of all live births", a curiously exact estimate, but one which seems out by a factor of 10. We are told that

"authorities now estimate that seven to eight per cent of the US population is adversely affected by one or another form of heritable disease" (p 14) while the next page includes gout and diabetes as genetic diseases, which certainly helps the percentages. We are probably all potential diabetics. Heart disease emerges again on page 21: this time 20% of cases are attributable to one of three genes and 5% are polygenic (what about the other 75%; can anything be non-genetic and non-polygenic?). Those three unspecified genes are said to be the most common disease-producing genes. Estimates of hard cash are made with equal abandon. Death from Tay-Sachs disease is costed at \$35,000, which seems a lot unless it includes the artificial piping of both food and air to the dying. Earlier, the booklet states that "specific genetic factors are involved in approximately one-fifth of all heart attacks". What does this mean? Why not incriminate the Y chromosome, which is surely genetic, and is found in at least four fifths of victims of heart attack?

How can the economic custodians of medical research in a country which has such numerous claims to excellence in both aim and achievement, be associated with the publication of such a confused and contradictory document? For whom can it be meant? Why are the achievements made by other routes, such as safe blood transfusion, the 'cure' of rhesus disease by exchange transfusion, and its prevention by immunisation, not worthy of mention? Are not the triumphs of haemophilic therapy worth a sentence? The US decision to funnel funds into 10 centres seems strange, since excellence cannot be constrained, even in smaller countries; is this booklet for congressmen who think their constituents neglected? Or is it what the *Observer* calls "research by public hysteria"?

Genetic research needs money, and the excellence of this research in the US would seem to have suffered even more than that in most other countries during recent years. A pre-occupation with costing, with short term aims, and the throwing around of wild estimates of such measures of the genetic load as the number of recessives per gamete, or the number of dollars per death, does little to reassure admirers of American genetics that the future will be worthy of the past.

It is tempting to dismiss this as a mere manifestation of bureaucratic immaturity, hardly worthy of comment. The matter is however, too important to be glossed over in this way. There is nothing more important than the orderly survival and civilisation of our own species.

J. H. Edwards

international news

THE absence of an official statement from the World Meteorological Organisation (WMO) after the recent meeting of its working group on stratospheric and mesospheric problems is being interpreted as an indication that WMO sees no danger of imminent disaster caused by the depletion of the Earth's protective ozone layer. This is in spite of calculations presented to the group to the effect that long term depletion of stratospheric ozone by the continued release of freons at 1972 levels could amount to more than 10%, and that ultraviolet radiation reaching the ground could increase by 2% for every 1% decrease in ozone. The group apparently wrote into its deliberations that it was working on a "factor of uncertainty" of about 2, which, at worst, would indicate a 20% depletion of stratospheric ozone, with a corresponding increase of 40% in radiation levels. This would be serious by any estimate.

The working group on stratospheric and mesospheric problems was set up under WMO's Commission for Atmospheric Sciences, and included many of the world's leading experts in this field: physicists, stratosphere chemists, experts on ozone, on the physical and chemical behaviour of the stratosphere,

WMO silent on ozone depletion

from Peter Collins, Geneva

and those concerned with evolving models for the study of what goes on in the stratosphere. The group was concentrating principally on the chlorofluoromethanes (freons) resulting from the use of certain aerosols and certain types of refrigerator, and which have recently been the subject of alarm, especially in the US. It is the first time that these substances have been considered by WMO at this level and it is indicative of the increasing attention being paid there to the broader environmental aspects of air pollution.

As summed up by a participant, the meeting concluded that calculations on an average, world-wide basis, ignoring latitude and the longitude and using one-dimensional models, indicate that the present anthropogenic contribution to the depletion of ozone by freon 11 (CFCl_3) and freon 12 (CF_2Cl_2) already in the stratosphere is 0.5 to 1.00% of the total amount of ozone. The long-term steady state effects of continued release of these substances at 1972

world rates would result in about a 10% depletion with an average factor of uncertainty of about 2. The effects of this 10% on the thermal regime of the stratosphere might be noticeable but are still not clear; the consequences of any such changes on tropospheric weather systems are likewise uncertain. It has also been estimated that a 1% decrease in the total ozone amount would permit a 2% increase in ultraviolet radiation at ground level, always assuming clear weather.

The group also discussed other pollutants such as bromine and nitric oxides, but it has been pointed out that the freons arising from human activities at the Earth's surface are very much more serious than anything that could happen from the use of aircraft, including nitric oxide emissions which are of such concern to the anti Concorde lobby. No official report of the meeting is likely to be forthcoming for some months, and even then it is likely to express the conclusions with great caution. One reason for this is that we still know very little about what goes on, chemically and physically, in the stratosphere. Here, the group did express itself clearly in agreeing on the need for more data from observation. □

NOT quite two years after the publication of its third and final report recommending major changes in the formulation and implementation of science policy in Canada, the Senate's special committee on science policy is preparing for an investigation of how effectively those changes have been carried out.

Senator Maurice Lamontagne, the committee's chairman, says letters went out in September to the Ministry of State for Science and Technology (which was created in part as a result of the committee's recommendation) and the Science Council of Canada, asking them to prepare briefs for a new set of hearings to begin in November.

Since the publication of the last volume of its report in the autumn of 1973, the committee has been concerned with planning a major conference on future research for decision makers at various levels of national life to attend. That involved preparing background papers for an area of interest largely neglected by other institutions in Canada. The committee also proposed establishment of two

institutions: a Canadian Centre for Future Studies and a commission called Futures Canada.

Much to its obvious chagrin, the federal government decided last summer to accept the thrust of the Senate committee's recommendations, but to

Lamontagne revisited

from David Spurgeon, Ottawa

take the matter out of its hands and entrust it to the recently formed Institute for Research on Public Policy.

This left the committee without a job.

Senator Lamontagne's response was to propose a return to its former mandate, "not to start a new inquiry but to uncover the areas where our demand for change and improvement has been met with minimum compliance, or simply with autocratic and bureaucratic rejection."

Even before the new hearings begin,

the Senator is less than pleased about governmental response to his recommendations. He sees MOSST (the science ministry) as possessed of "suicidal" tendencies (some 30 senior employees were let go recently), and he finds no technological strategy developed by the Department of Industry. "Government support for science, technology and innovation," he told the Senate, "continues to be inadequate, uncoordinated and wasteful."

The Science Council of Canada may welcome the committee's new activity, because it seems to have been eclipsed more and more as a result of the creation of MOSST. But it is difficult to believe either the government or MOSST will be exactly overjoyed. The ministry seems to have been slipping slowly into oblivion in recent months, and just as the new part-time minister, C. M. Drury (who also held the portfolio of public works) had begun to counteract this drift with a public definition of its role, he found himself appointed interim finance minister as a result of the resignation of the former minister, John Turner.

Pauling comes in from the cold

PRESIDENT Ford last week invited 13 scientists to the White House to receive the National Medal of Science, the most prestigious scientific prize offered by the federal government. For one of the recipients, Linus Pauling, the event had added significance, for it marked the end of a long and bitter period during which Pauling had been virtually ostracised by the White House for his outspoken political opinions and his opposition to nuclear weapons.

Although he has received almost every possible scientific accolade, including two Nobel Prizes, Pauling has suffered a number of direct reprisals for his political views, and he has repeatedly been ignored when the National Medals of Science have been handed out. The latest such rebuffs came during the Nixon Administration when Nixon, who was not known for honouring his enemies, twice overruled Pauling's nomination for the prize.

Pauling's political troubles began in the early 1950s, during the anti-communist witch hunts which culminated in the rampagings of Senator Joe McCarthy. Accused of being a Communist sympathiser, he was denied a passport in 1952 to travel to Britain for a meeting of the Royal Society, and he was again refused a passport a year later. He was also refused a government research grant in the early 1950s for political reasons.

Such overt reprisals lessened a little after he was awarded the Nobel Prize for chemistry in 1954, in recognition of his pioneering work in unravelling the nature of the chemical bond. He was, at least, granted a passport. But Pauling continued to needle successive Administrations by attacking nuclear weapons testing, foreign policy and, in the 1960s, the Vietnam war. Although his actions brought rebuffs at home, Pauling's political activities brought him the Nobel Peace Prize in 1962 and the International Lenin Peace Prize in 1971.

There was, however, one occasion on which the White House temporarily suspended hostilities against Pauling. Soon after he was elected, President Kennedy invited Pauling, along with every other American Nobel Prize-winner, to a White House dinner. Pauling accepted, but before attending the event, he led a protest demonstration outside the White House gates against nuclear weapons testing.

The citation which accompanied his National Medal of Science states that the award is "For the extraordinary scope and power of his imagination, which has led to basic contributions in such diverse fields as structural chem-

Pauling at the White House with a friend (pic: Washington Post).

istry and the nature of chemical bonding, molecular biology, immunology, and the nature of genetic diseases". Pauling, who is now 74, accepted the prize with a broad grin, accompanied by the clicking of a multitude of cameras.

Other recipients of the award were Britton Chance (University of Pennsylvania), Erwin Chargaff (Columbia University), James Neel (University of Michigan), James Shannon (former Director of the National Institutes of Health), Rudolf Kompfer (Stanford University), Ralph Peck (University of Illinois), Abel Wolman (Johns Hopkins University, now retired), Kurt Godel (Institute for Advanced Study), Nicolaas Bloembergen (Harvard University), Paul Flory (Stanford University), William Fowler (California Institute of Technology) and Kenneth Pitzer (University of California, Berkeley).

● At the annual International Astronautics Federation congress this week in Lisbon, the Guggenheim International Astronautics Prize, awarded by the International Astronautics Academy, goes to Oleg G. Gazenko, now Director of the Institute of Biomedical Problems in Moscow. More than anyone else in either the US or Soviet space programmes, he has made a concerted attack on the daunting problems of placing and maintaining man in space—and it is now hard to remember that before 1957 many

physiologists were convinced that such a venture would only prove a costly catastrophe. The line of development conceived and carried through by Gazenko and his colleagues can be considered to have culminated in the effective compromise of the Apollo-Soyuz joint test project, in which the Soviet life support philosophy and that of NASA were blended rather than unilaterally bent.

Oleg Gazenko's involvement with the physiological problems of space flight and life support for long manned spaceflights goes back beyond 1957, to the time when the first Soviet physiological experiment was carried out in space—involving the dog Laika in the second *Sputnik*. The choice of the dog as the test animal for pioneering *in vivo* experiments in space may be attributed to Gazenko, although it conformed equally with classical Pavlovian behaviourism favoured by the Soviet medical establishment.

Since the mid-1960s Gazenko has been in the thick of the project (finally agreed in principle in 1964) for joint publication of US and Soviet space medical and biological experience (*Foundations of Space Biology and Medicine*). Recently, American research and competence in space biology and medicine has more than caught up and it has assumed for a year or two that Gazenko had lost status. This award should set the record straight. □

AN extraordinary period of expansion in the life of Israeli universities is coming to an end. After a quarter of a century during which student enrolment has increased almost 40 fold (in contrast to a five-fold increase in the general population), it is now up by only 5 or 6% a year. And severe financial problems have virtually brought an end to the spate of multi-million pound building projects so characteristic of the last 25 years.

Not all universities have been affected in the same way by the new situation. Though the 50 year old Hebrew University of Jerusalem is actually expecting a decline in enrolment this year, the newer institutions of higher learning in Haifa, Tel Aviv and Beersheba are still growing, albeit at a slower pace than previously.

Off the record, some professors argue that Israel does not need even its existing seven institutions of higher learning to handle the current student population of some 60,000 (which gives Israel about the same percentage of university students as the countries of western Europe). Since, however, it would be politically impossible to shut one down, all the Council for Higher Education could do was to ban the establishment of new universities (in the foreseeable future) and to crack down on plans to create new faculties at existing universities, particularly where they duplicate programmes already available elsewhere in Israel.

Reaction to the situation has varied from campus to campus. The President-elect of the Weizmann Institute, Professor Michael Sela thinks that Israeli institutions of higher learning should, in the circumstances, "use their shrinking resources to raise academic standards rather than add floor space". And Professor M. Z. Kaddari, until recently Rector of Bar-Ilan University, wants to cut down on the intake of students, not only because of budgetary problems but also "to avoid the creation of a disillusioned academic proletariat".

Naturally enough, the President of the Technion Institute of Technology, Amos Horev, believes that, regardless of the number of students, a greater percentage of them should be studying engineering lest a shortage of engineers frustrate Government plans to double Israeli industrial output by 1980.

Whatever the logic of Horev's argument, priorities in the sphere of higher education will have to be more clearly defined than they have been in the past, when money seemed to be available for everything at once. The boom is over.

● Despite their financial problems, or possibly because of them, institutions of higher learning are strengthening their ties with local industry. A recent con-

sequence of such cooperation is the Microviscosimeter MV-1, an Israeli instrument expected to facilitate the early detection of leukaemia, which was this week named one of the 100 most innovative products of the year by *Industrial Research*, a US magazine.

The instrument was developed by the Elscint Company of Haifa on the basis of studies carried out by young researchers Michael Inbar and Meir Shnitzky of the Weizmann Institute's Laboratory of Membranes and Bioregulation. It grew out of an

Letter from Israel

from Nechemia Meyers

apparent correlation discovered by Dr Inbar and Dr Shnitzky between the level of cholesterol in the cell surface membrane and the blood, and the development of leukaemia.

Named Israel's Outstanding Exporter of 1974 for its large overseas sales of medical and laboratory equipment, Elscint is particularly proud of the fact that its MV-L is sharing honours this week with instruments created by a group of international giants.

● Another achievement of local, science-based industry unveiled recently is a mobile pilot plant for processing sewage that provides as end products both purified water (suitable for irrigation and almost suitable for human consumption) and concentrated algae for use as high-protein animal feed.

Built by the Membrane Division of Israel Desalination Engineering Ltd (IDE), under the supervision of Dr S. Sachs, the installation, unlike treatment plants now in operation, does not require the introduction of algae-killing lime or alum into its oxidation pools. Instead, it concentrates and purifies the sewage by low pressure ultrafiltration, using membranes developed specifically for the task.

It is not yet possible to estimate the cost of building and operating IDE units on a commercial basis, but an important factor in costs—the energy input required—is relatively low because the purification process can be carried out at a pressure of 7 or 8 atmospheres, as compared to 60 or 70 atmospheres in conventional reverse-osmosis systems. Moreover, the low pressure permits the unit to be built with less expensive materials than would otherwise be required.

When expenses are calculated, one must also consider the fact that the algae 'left over' should bring in substantial sums of money.

Economic considerations in Israel

may be rather different from those of other countries, as additional water supplies are urgently required here, almost regardless of cost. But both the Treasury and the taxpayers would be most grateful if recycling a larger part of Israel's sewage made it possible to delay the construction of large scale and very expensive desalination plants.

● A more controversial scheme for increasing water supplies has come from the Ministry of Agriculture's Soil Conservation and Drainage Department. Ministry experts claim that transforming 85,000 acres of shrub-covered Galilee hillsides into pasture land would save 85 million cubic metres of water because grass requires less moisture than shrubs and the "surplus rain" would seep down into the aquifer. Moreover, they add, the new grasslands would provide enough forage for raising 24,500 cattle each year, as well as creating an excellent recreation area.

The scheme has, however, been severely criticised by, among others, Professor Zeev Raveh of the Technion Institute Faculty of Agricultural Engineering. "If the plan were implemented," he declares, "it would supply the country with very little additional water or meat, and, far from creating a new recreational area, it would gravely endanger the ecological balance of one of Israel's few remaining focuses of natural beauty and rich biological diversity."

Pointing out that the Ministry of Agriculture plan has so far only been tested on a carefully tended, one and a quarter acre plot, Professor Naveh doubts very much whether the lessons learned there are applicable over a much wider and more diverse area. He notes, for example, that uprooting shrubs is a very expensive process if it is to be effective (costing several times more than was estimated by Ministry planners) and, he adds, there is no certainty that the new vegetation that takes over will be suitable for grazing purposes.

Though a few months ago it was planned to implement the Ministry of Agriculture scheme at the rate of 8,500 acres a year, public protests have prompted the Government to undertake further studies before uprooting any shrubs on a large scale. At the same time, measures will undoubtedly be taken to foster the multipurpose use of Israel's extremely limited areas of land. Professor Naveh, for his part, thinks that they must be carefully designed to suit the requirements and possibilities of each site so as to achieve a maximum degree of economic benefit (in the form of increased water yields, grazing land and timber) while ensuring that key elements in the ecosystem are not undermined.

correspondence

Moon

SIR,—One must assume that at the beginning of each year the Editor of *Nature* writes in his diary, in the appropriate place, "Be sure to include an article designed to discourage readers from attending the International Conference on the Unity of the Sciences". Having attended last year's ICUS conference, I can vouch for the fact that the majority of the eminent names mentioned in the advance publicity did in fact attend the conference and make contributions. As far as I am aware, no-one present was dissatisfied at the proceedings, and at the end I was left with the impression that the conference had succeeded in achieving the aim of any conference, namely of allowing free exchange of ideas on important topics.

Regarding the sponsorship of the conference, from his opening address I gained the impression that at any rate some of the Rev. Moon's motives are at least as worthy as those of such well known conference sponsors as the armed forces. As to the rest, news (as reported by you) is capable of being distorted in many ways, but whatever the true situation may be, I find it difficult to accept from a reputable scientific journal something which one cannot interpret as anything other than a deliberate attempt, for ideological reasons, to sabotage a conference by discouraging potential participants from attending.

Yours faithfully,

B. D. JOSEPHSON

Cambridge, UK

Silly in the head

SIR,—Regarding the "silly season for newspapers" as discussed in *Nature* (August 28), how about the headline for a recent Independent Television News at Ten—"British scientists discover origin of Universe"?

Yours faithfully,

JOHN WOODSIDE

Cambridge, UK

SIR,—Herewith some suggestions for your silly headlines list:

Britain fastest in entropy acceleration studies—official
Plutonium for Arabs in genetic manipulation research deal
Pugwash scientists named in SALT talks sell-out allegations
Ice-age predictions snowball as funds frozen

Nature readers in shock titles scandal
—alleges Longford

Yours faithfully,

BERNARD MEARES

Copenhagen, Denmark

Stop metrication

SIR,—On August 28 you referred to the pointless advance of metrication. There is one area where good sense has a foothold, even in France. Whether in Notre Dame or the humblest village church, organ pipes are still measured in feet. I could not think of foundation stops of 2.4 m or adding the brilliance of a 0.3 m rank.

Common sense still prevails over logic in one area—I am sure that there must be others.

D. C. HARDWICK

London, UK

CAB directors

SIR,—It is unfortunate that your correspondent in his article on the Commonwealth Agricultural Bureaux (August 14) spoiled an otherwise factual and informative piece by an inclusion of quite unmerited criticism of CAB directors.

As your correspondent says "the bureaux have maintained and justified their reputation for providing the world's best and most comprehensive source of information in the fields they cover". The reputation has been gained not by the central management but by the individual bureaux under the management of the directors. That changes are needed to modernise the bureaux structure is acknowledged by the staff, and the Institution of Professional Civil Servants (IPCS) has put forward on their behalf proposals which we hope the CAB management will adopt but which will be rather

different from those proposed by the Civil Service Department review team.

The CSD review team made recommendations which implied criticism of the central management rather than of the staff or the directors of bureaux. The misuse of computer printing, resulting in an increase in the time taken to publish abstracts as compared with the time when directors were completely responsible for publication, is an example. Clearly there is room for improvement in the management of computer services. Certainly to the extent that it is possible, collaboration with other agencies doing similar work is desirable. But your correspondent is wrong in assuming that there is not already collaboration with AGRIS, the bureaux already scan UK journals for AGRIS and make no charge for this service.

The report of the review team stress on the economies in staffing which would result from operating the abstracting and editorial services on a commercial basis. We believe that this could be achieved only by lowering the standards of the service and this would seriously reduce its value to its users. An important feature of the CAB service is its abstract enrichment and this could not be maintained if commercial viability were the first consideration. The review team made no attempt to test its assumptions by market survey. Enquiries we have made from a necessarily small sample of eminent scientists in the agricultural field have all met with the response that the CAB abstracts must be maintained at their present high quality if they are to be of value. By all means let us have additional effort to market the CAB's products (and the staff will not be greatly concerned whether this job is described as "marketing" or "circulation and services") but the article for sale must be first class.

Whatever changes are made in procedures and staff structures they will be successful only if they have the whole-hearted cooperation of the staff. A lowering of standards would lead to loss of job satisfaction for the staff and a drop in morale. Staff morale will not be improved by suggestions such as those made by your correspondent that the staff are responsible for the difficulties which are solely attributable to bad management.

EDWARD HEWLETT

IPCS, London, UK

news and views

LESS than a year after their discovery it was widely accepted that pulsars are rotating neutron stars, with high magnetic fields and consequently with a very energetic co-rotating magnetosphere. Progress beyond this basic interpretation has been slow, not through a lack of experimental data but through the sheer unfamiliarity of the physics involved in these strange objects. The solid state physics has to deal with densities approaching $10^{14} \text{ g cm}^{-3}$, with a composition varying from a neutron superfluid to a crystalline crust mainly composed of iron nuclei. The very strong magnetic field is sustained by the superconductivity of the neutron star, and itself modifies the crystalline structure of the crust. Conditions in the magnetosphere are even more bizarre, with complete charge separation and vacuum spark gaps as possible features.

The difficulty in interpreting the radio pulses, which provide our only observational material on nearly all of the pulsars, is that they originate in only a local region of the magnetosphere, and their radiation processes are limited indicators of the behaviour of the rest of the neutron star. Furthermore, they have very complex structures, which we cannot easily interpret without knowing more about the radiation process and the precise location of the emitter in the magnetosphere.

Recent work on pulsars at Jodrell Bank has used the timing of the radio pulses to investigate the slow-down of rotation of the neutron star. The

Physics of pulsars

from F. G. Smith

slow-down is a consequence of radiation from the rotating dipole magnetic field, so that this investigation was using the radio pulses as an indicator of conditions within the star. Surprisingly it led to the suggestion that the magnetic field decays with a time constant of a few million years, which is in conflict with present theories of the superconducting interior of neutron stars.

Another investigation, also related to the age and evolution of pulsars, but which refers to the magnetosphere rather than the star itself, is reported in this issue of *Nature*. Ritchings and Lyne (page 293) have found a new orderliness in the apparent disorder of the structure within radio pulses. Some pulsars, and particularly the older ones as shown by the previous investigation, have "drifting sub-pulses". An individual radio pulse in these pulsars consists of one or two narrow sub-pulses, which can be seen in several consecutive pulses but at slowly varying times within the pulses. The "drift" in time can be either earlier or later, although until recently it was thought that all drifts were earlier. The remarkable observation now reported is that these two cat-

egories are simply divided between those pulsars with slowly lengthening periods, which drift earlier, and those with rapidly lengthening periods, which drift later.

The most important conclusion must be that there is after all some simple classification and evolution in the pulsars, whose behaviour may perhaps be regulated mainly by the strength of their magnetic fields. We do not know at all how the drifting itself occurs, although there have been some interesting suggestions about the drifting of discharge paths across a spark gap near a magnetic pole. But we can at any rate rule out those theories which allow only one direction of drift, or those in which the direction was regulated by the aspect of the rotating star as seen by the observer.

The physics of the emission process is not revealed by the drifting phenomenon, since this may occur in a region remote from the emitter. For example, drifting in a spark gap at the poles provides a lateral movement in a stream of particles, which then sweep across an emitting region which might be close to the velocity of light circle. There is some evidence in favour of this location for the emitter from the work on pulsar slowdown rates, which indicate that the pulsars stop emitting when the magnetic field in that region falls below a critical value. On present evidence, the behaviour of pulsars seems to be completely dominated by the strength of the magnetic field.

SEAMOUNTS are active or extinct conical or flat-topped ocean floor volcanoes with elevations of at least 1,000 m, the majority not rising above sea level. They occur throughout the world's oceans but are particularly associated with the Pacific where, according to Menard (*Experientia*, **15**, 205; 1959), there are some 10,000. Several hundred of the Pacific volcanoes form linear chains (the best-known of which is the Emperor-Hawaiian chain) which are widely believed to result from the motion of the Pacific plate above hot spots with roots in the mantle. Most seamounts, however, are apparently individual bodies located at random on the ocean floor, although they tend to lie in clusters or bands.

As long as the oceans were thought

Do seamounts form near ridges?

from Peter J. Smith

to be permanent, the points of origin of seamounts posed no particular problem; volcanoes erupted on the ocean floor and thereafter remained fixed in position. But moving sea floors have introduced an ambiguity. Leaving aside the small proportion of seamounts aligned in chains, did the rest originate at random locations by some intraplate volcanic process or did they erupt near oceanic ridges and spread away to cover the ocean floor? As the number of seamounts per unit area of ocean floor does not seem to increase

away from spreading ridges (which means that the density of seamounts is no greater in older than in younger sea floor), the random hypothesis seems the less likely; but this can hardly be said to be definitive evidence.

An obvious way of settling the matter would be to date both seamounts and the surrounding ocean floor; a seamount embedded in ocean floor of comparable age would then imply ridge formation whereas discrepant ages would imply random volcanism. Unfortunately, experiments along these lines have provided conflicting evidence. Fisher *et al.* (*Science*, **160**, 1106; 1968), for example, found that three seamounts near the East Pacific rise were apparently up to 40 Myr younger than the underlying crust. The age of the

crust was poorly defined at that time, however, and a more recent tectonic reconstruction of the region by Herron (*Geol. Soc. Amer. Bull.*, **83**, 1671; 1972) has reduced the seamount-ocean floor age difference to between 5 and 6 million years. An even closer age agreement was obtained by Ozima *et al.* (*Earth planet. Sci. Lett.*, **8**, 237; 1970) for three Pacific seamount dredge samples (two Cretaceous, one Pliocene). Dymond and Windom (*Earth planet. Sci. Lett.*, **4**, 47; 1968), on the other hand, found that although two seamounts resting on Cretaceous crust southwest of Hawaii were also Cretaceous, a third was less than 1 Myr old.

In an attempt to resolve such conflict, Clague and Dalrymple (*Geophys. Res. Lett.*, **2**, 305; 1975) have now dated four seamounts in the central North Pacific—two from the Hawaiian ridge (Wentworth Seamount and Necker Island) and two from the Musicians Seamounts (Rachmaninoff and Khatchaturian). The samples from Necker and Wentworth are, respectively, at least 60 and 40 Myr older than the adjacent Hawaiian bodies as predicted according to the hot spot-plate motion hypothesis, and thus conflict with the concept of a Hawaiian chain ageing progressively westward. Rather than taking these results to disprove the age progression, however, Clague and Dalrymple propose that Wentworth and the northern part of Necker are Cretaceous seamounts that predated the formation of the Hawaiian chain and later became incorporated within it. Indeed, on the basis of seamount densities within the Pacific in general and in the area surrounding (but excluding) the Hawaiian chain in particular, the incorporation of at least this number of older seamounts is to be expected.

Assuming that Wentworth and Necker are unrelated in origin to the main Hawaiian chain, therefore, it only remains to compare their ages with those of their respective areas of surrounding ocean floor. Unfortunately, this is not easily done, largely because of the lack of magnetic anomalies in the vicinity of the Hawaiian ridge. From available fossil and radiometric age data and by extrapolating magnetic data from further afield, Clague and Dalrymple nevertheless conclude that Necker Island and possibly Wentworth Seamount are only slightly younger than their underlying crusts; likewise, the Rachmaninoff and Khatchaturian Seamounts, and two other Pacific seamounts previously well dated by other workers. Thus although the data are few and one or two discrepant seamount-crust ages still remain (notably that of Dymond and Windom), Clague and Dalrymple propose that most Pacific seamounts did indeed form on or near the East Pacific rise. □

Cyclotrons of all shapes and sizes

from E. G. Michaelis

The Seventh International Cyclotron Conference was held in Zurich on August 18–22 at the Swiss Institute for Nuclear Research.

THOUGH advancing into middle age and occasionally overshadowed by its Gargantuan progeny the cyclotron continues to develop vigorously, and after a series of facelifts its original passport photograph still current in physics textbooks is anything but a true likeness. The art of cyclotron construction remains challenging and cyclotrons serve a wide spectrum of scientific disciplines. Its devotees are still growing in number and budgetary restrictions have not diminished their enthusiasm or their ingenuity.

The Swiss Institute for Nuclear Research (SIN) welcomed more than two hundred participants from twenty-one countries with Swiss hospitality, and the report of the successful commissioning of the world's most powerful isochronous cyclotron by the Institute was a major contribution to the conference. News of similar successes achieved with large machines in Vancouver and Indiana proved that present designers can meet almost any challenge in this field.

Most of the 90-odd cyclotrons forming the subject of the conference are isochronous and sector focusing. Like the classical cyclotron they operate at constant orbital frequency but maintain this to relativistic ion energies by a magnetic guidefield increasing with orbit radius. Edge focusing between sectors of higher and lower field provides the axial stability which is absent

in a cylindrically symmetrical, radially increasing field.

In Spiral Ridge machines the sectors are curved to increase axial focusing, and in Split Pole cyclotrons the magnet poles are restricted to the high-field regions to increase the azimuthal variation of the field. The largest machines of this kind, the 590 MeV proton ring at SIN and TRIUMF, and the 520 MeV H^- accelerator at Vancouver combine both features. The magnetic fields in sector-focusing cyclotrons are subject to close tolerances and the ions are accelerated rapidly by high electric fields in two or more accelerating gaps to minimise the effects of local instabilities. Since technology and computer-aided design have made it possible to meet these conditions cyclotrons have become ever more powerful and versatile, many permitting the acceleration of a wide range of ions to prescribed peak energies. While problems of orbit stability are therefore largely resolved, those of ion sources, injection and extraction still limit performance and received much attention at the conference.

The growing interest in heavy, multi-charged ions calls for new ion sources to avoid the present need for several accelerators in cascade with ion stripping to higher charge states between successive stages. Reviewing the field J. Arianer (IPN, Orsay) showed that electron beam sources furnish more intense beams of highly stripped ions than the conventional PIG source or present laser sources.

Large and complex sources cannot be mounted in a cyclotron, and polarised, H^- and heavy ions are usually injected after some pre-acceleration. Only large split-pole machines permit mid-plane injection while particles are axially injected and deflected into the mid-plane of smaller machines. Interesting progress in mid-plane trochoidal injection however was reported by W. van Kampen (Delft Technical University) 200 keV protons are made to precess along a sector edge towards the middle of the cyclotron, where a suitably perturbed field gradually centres the orbits.

Ion extraction becomes more difficult as the separation between successive turns decreases with increasing particle energy, but notable successes in the extraction of energetic ions were announced at the conference. H. Willax (SIN, Switzerland) reported that more than 90% of the 590 MeV protons in the SIN accelerator can be extracted thanks to an energy gain exceeding 2 MeV per turn. J. R. Richardson (TRIUMF, Vancouver) described the simultaneous extraction of two proton beams of different energies from the large H^- accelerator and CERN achieved an extraction efficiency ex-

A hundred years ago

The celebration of the fiftieth anniversary of the opening of the first railway between Stockport and Darlington is attracting the notice of the French papers. Baron Charles Dupin, who published his celebrated work on Great Britain in 1826, described to the Institute that locomotives could never move, owing to the weakness of their hold on the rails, and that the use of horses could not be dispensed with. Baron Charles Dupin's reputation was so great that the truth of the statement was taken for granted from *Nature*, **12**, 483; September 30, 1875.

THE trend towards simplifying ecosystem complexity for comparative purposes by the use of common energetic terms often causes confusion by obscuring basic principles. The 'standing crop' of an ecosystem is one such term which indicates how much energy there is in the system at any one time. But the total amount of, say, primary production in energy terms available may not be the same as the amount actually available to the herbivores which feed upon it. Thus the figure for standing crop may be a red herring to anyone wishing to determine whether food is limiting in the ecosystem. A rule of thumb guide to consumption of grassland vegetation by herbivores is that rarely is more than 10% of annual primary production actually eaten (Wiegert and Evans, in *Secondary productivity of terrestrial ecosystems*, 449 (edit. by K. Petruzewicz) (Polish Academy of Sciences, Warsaw, 1967)), and in many instances 2% is nearer the mark (Grodzinski, *Acta theriol.*, 16, 231; 1971). On the face of it, therefore, food would not seem to be a limiting factor to herbivore populations.

The fallacy in this argument is to equate primary production standing crop with food. Food is more than just energy, and for most large ungulates a constituent of major importance is crude protein. Bredon *et al.*, among others, concluded that when the crude protein content of forage dropped to less than 4% dry weight, plant material ceased to function as food and ungulates feeding on it started to lose weight (*J. agric. Sci. Camb.*, 61, 101; 1963). Death does

not follow immediately and cattle kept on low quality grass continue to feed, but they face mounting physiological stress.

A careful demonstration of the hazards inherent in the standing crop approach to ecosystem dynamics is provided by Sinclair's recently re-

Standing crop \neq food

from our *Animal Ecology Correspondent*

ported studies on limiting factors in the Serengeti (*J. Anim. Ecol.*, 44, 497; 1975). He points out that herbivores—ungulates, small mammals and grasshoppers—consume 27%, 38% and 14% of the annual primary production of tall grassland, short grassland and kopje country respectively. This leaves a large portion of the annual production for detritivores and for fuelling fires. Why is it not used to support higher populations of herbivores? The answer is that for a part of the year it is unavailable as food, much of the protein and carbohydrate in the leaves having returned to the roots. Sinclair's figures show that from a spring level of 8% crude protein, dry season grass contains between only 1% and 3%. In the tall grassland, food required by herbivores is in excess of that available for the duration of the dry period—July to September. This is associated with a drop in small mammal and grasshopper populations and hence foraging pressure, but is compensated for by an increased intake by ungulates. Monitoring bone

marrow fat levels in wildebeest over the year reveals that they fall slightly during the dry season indicating some degree of physiological stress experienced at this time. In the kopje country where ungulates were seldom seen, herbivore food requirements outstripped production for a much shorter period largely because of the rapid decline in rodent and insect numbers. This strategy for accommodation to sudden unavailability of food is open only to small herbivores with fast growth and reproductive rates and is barred to ungulates who must tighten their belts and just make do.

Hairston *et al.* and other workers have suggested that since herbivore populations consume so little of the primary production they cannot be limited by lack of food, and so must be limited by parasites, predators or disease (*Am. Nat.*, 94, 421; 1960). The available evidence simply does not support this hypothesis. Sinclair is right to point out that an important implication of Hairston's hypothesis is that interspecific competition and niche diversification is precluded. There is no evidence that this occurs and plenty that it does not. Furthermore, consideration of mean annual values hides fluctuations not only in crude protein content but perhaps also in trace elements and other specific nutrients at certain times of the year. Availability of primary production as food is also affected by the physical correlates of feeding; crushing, despoiling and dropping. It is also affected by the nutritional and other needs of different age and sex classes in the populations.

ceeding 70% in its reconstructed synchro-cyclotron.

Work on heavy-ion acceleration was reported from several laboratories. A 25 MeV Tandem Van-de-Graaff under construction at Oak Ridge National Laboratory will inject ions into an existing cyclotron and will raise its energy to 800 MeV for ions of mass 160. M Gouttefangeas (CEA, Saclay) described a recently authorised French project in which three cyclotrons in cascade will accelerate the heaviest nuclei to 10 MeV per nucleon.

The large, split-pole cyclotrons favoured at present make for easy acceleration and extraction but require much steel and expensive buildings. Much more compact constructions can be achieved by using superconducting coils to provide fields of order 5T and the conference learnt of projects for such "superconducting" cyclotrons at the Lawrence Berkeley Laboratory and at Chalk River, Canada. Michigan State University is constructing a super-

conducting cyclotron magnet in order to study the problems posed by this new technique.

A tantalising project for a 100 mA 800 MeV proton cyclotron was described by Yu N. Denisov (JINR, Dubna, USSR), but its estimated radio-frequency power of 76 MW made it seem somewhat unrealistic.

Although primarily a gathering of accelerator physicists and engineers the conference devoted several sessions to the applications of cyclotrons and the range of topics proved the cyclotron to be a maid-of-all-work. The measurement by surface activation of abrasion in slurry-carrying ducts or of railway wheels, the determination of the fluorine content of a cup of tea by charged particle activation analysis, the study of nuclear level structures and excitation functions, radiation damage in reactor materials, the production of isotopes for medicine, neutron therapy, proton radiography and surgery are only a few of the topics covered by

various contributions.

M. M. Kligerman (University of New Mexico) reported on a comparative test of a treatment of skin melanoma by pions and X rays. The dramatic superiority of pions is a challenge to accelerator designers. A panel discussion on "Accelerators for Hospitals" reflected the difficulties, but tended to favour a proton-accelerator of variable energy.

The conference participants were able to visit the cyclotrons and experimental installations of SIN where a biomedical pion-channel and an eight-metre superconducting solenoid providing record fluxes of muons were of particular interest.

Professor M S Livingston, the co-inventor of the cyclotron, reviewed its early history in a delightful and informative after-dinner speech. Dr R Wideroe, the inventor of resonant acceleration also attended the conference and one may hope that the two veterans were pleased with the development of their brain-child. □

Satellites to the fore

from W. H. McCrea

EARTH'S satellite the Moon is not only the astronomical body other than the Earth about which most is known, it is also the astronomical body about which knowledge has increased most rapidly in recent years—thanks to the spectacular successes of the Apollo and Luna missions. Even more recently, Pioneer 10 and 11 have provided invaluable new information about the Galilean satellites of Jupiter. At the present time, therefore, astronomers are more satellite-minded than ever before. Above all, they are interested in the origin of satellites because this may provide a check upon, or even a clue to, the origin of the planets. After all, astronomers have only the one planetary system to study, whereas they have six satellite systems; so it is reasonable to think that the satellite problem might be solved before the planet problem.

T. Gold has reviewed the situation and made a number of suggestions (*Icarus*, **25**, 489–491; 1975). He begins by asserting that all planets for which satellite orbits would be stable do possess satellites, claiming that for Mercury the solar perturbation is too large, that the retrograde spin of Venus would cause satellites to spiral into the planet through tidal friction (but I think he means that the slowness of the spin of Venus would render it retrograde as seen by any possible satellite), and not mentioning Pluto. Anyhow, Gold is obviously correct in remarking that satellites are a common feature of the Solar System, and this stimulates him to seek a process of formation of the widest possible applicability. In general terms, he appeals to the dynamics of grains in the presence of massive gravitating bodies (Sun and planets) and of a resisting medium (neutral and charged particles and photons). If initially a lot of grains are moving at random in a gravitational field under the action of no other forces, the motion remains random, that is, it is conservative, and there is no tendency for the motion or space-distribution to become systematized in any way. But matters are different if dissipative forces play a part. If there are inelastic collisions between the grains themselves, then there may be focusing into the 'accretion streams' or 'jet streams' considered by some cosmogonists to be essential for the development of the Solar System. If there is a dissipative frictional drag exerted by a diffuse medium in the system, even at a stage when interaction between the grains is unimportant, there may be accumulation of grains in resonant bands in the

gravitational field of the moving planets. Both types of behaviour may be included under the heading of gravitational focusing. The novelty of Gold's discussion is to suggest a crucial cosmogonic role for the second type.

In bald terms the notion is: In the 'early solar nebula' grains were plentiful from direct condensation and from collisions between larger bodies of material. Under the action of the general gravitational field and the 'drag' forces, a grain near the central plane would normally spiral inwards or outwards from the Sun. Such spiralling could, however, be halted or speeded up if the motion became resonant with that of an orbiting planet. Thus lanes of accumulation or avoidance would have been formed. Here Gold remarks in passing that a lane of accumulation could be favourable for 'snowballing'; he suggests this as an explanation of the asteroids in Trojan orbits. He remarks too that in regard to any particular lane at any particular epoch there could be selection with respect to grain size or grain composition.

The main suggestion is that, material having been concentrated into a well-defined lane by resonance effects, when the resonance was broken, such material continued in a well-defined stream though once more in spiral motion; further, when it encountered a planet, there was a significant probability of its being captured into a ring round the planet. There would have been numerous cases of this happening throughout the system. Gold sees no serious difficulty in the passage from grains in circumplanetary rings to larger bodies, and the subsequent coalescence of these into one or more satellites round a planet as we now know them.

The interest of Gold's essay, one ventures to think, is its demonstration that the problem of the origin of satellites is still wide open. It was originally presented at a colloquium. It can scarcely have been intended to do more than throw out suggestions, for the treatment is non-quantitative throughout. This makes it difficult to comment further; however, when Gold writes, 'the step from circumplanetary rings to the formation of satellite bodies is not a difficult one and has been discussed on many occasions' one is bound to remark that although this has indeed been discussed often enough, one is not aware that it has ever been established that satellite bodies must form in these circumstances. Also, although there is much attractiveness in Gold's implication that all the regular satellites might have been formed by one and the same general process, the very great differences between the properties of the main satellites and the minor (regular)

satellites in the actual Solar System give strong indications of the operation of two distinct mechanisms of formation. Maybe we can look forward to a quantitative account of Gold's ideas in a form that could be more critically compared with observation. □

Nutrient balance during succession

from Peter D. Moore

THE developmental growth of an ecosystem, commonly termed succession, involves a steadily increasing biomass, reaching a maximum at the climax, or steady state, which is ultimately attained. The increase in living material during succession places a demand upon the inorganic, abiotic component of the system for those elements necessary for the construction of living tissues. Ultimately the biotic component thus becomes an important reservoir of nutrients—a feature which may contribute very considerably to the overall nutrient capital of an ecosystem (see *Nature*, **254**, 184; 1975). Actual data concerning the changing nutrient demand of the biotic component of an ecosystem during its development are, however, sadly lacking.

Experimental manipulation of watersheds in the Hubbard Brook Experimental Forest in New Hampshire, has provided a certain amount of information on which to speculate. Six small, undisturbed watersheds at this site have been studied intensively over a number of years and data concerning nutrient input from rainfall and output from stream drainage has been collected. In 1965 one of the forested watersheds (15.6 ha in area) was clear-felled and the resulting changes in the chemistry of the runoff waters were subsequently reported by Bormann, Likens, Fisher and Pierce (*Science*, **159**, 882; 1968). One of the most striking changes observed was the increased loss of nitrate nitrogen from the ecosystem following felling; a loss of $1.5 \text{ kg N ha}^{-1} \text{ yr}^{-1}$ occurred in a control forested watershed, whilst $58.1 \text{ kg N ha}^{-1} \text{ yr}^{-1}$ were lost from the clear-felled watershed. Many cations also increased in concentration in the runoff water, thus permitting the conclusion that disturbance led to increased leaching and therefore a reduced capacity for nutrient conservation.

Marks and Bormann (*Science*, **176**, 914; 1972) further demonstrated that revegetation of a disturbed area led to considerably diminished nutrient runoff and they concluded that the early stages of succession which were then

occurring placed a high nutrient demand upon the abiotic environment as the biomass was in a rapid growth phase.

A rather different approach to the problem of documenting the relationship between the stage of ecosystem development and its ability to retain nutrients has recently been made by Leak and Martin (*USDA For. Serv. Res. Note*, NE-211; 1975). They have examined six forested watersheds in the north-eastern United States and have attempted to determine the approximate time when they were last disturbed. Obviously this is a complex problem, since different stands of trees within a stream catchment will have had different histories. A number of stands (between 7 and 41) were sampled within each catchment and such characteristics as the evenness of age within the stand and the proportion of tree species normally favoured by disturbances were noted. In this way it was possible to rank the six sites according to their 'weighted average age'. The time which had passed since general disturbance within the study sites was found to vary between 65 and 200 years.

Streamwater concentrations of nitrate from these watersheds had previously been monitored and these bear an evident relationship to the age since cutting. The site with an average tree age of 65 yr had stream nitrate concentrations of 2.3 p.p.m. (compare recently clearcut areas with 10.3 p.p.m.). Sites with age 75–110 yr trees had 0.15 p.p.m. nitrate in the streamwater, those of 125 yr had 0.8 p.p.m. and those of 200 yr, 2.2–4.8 p.p.m. Similar results have apparently been obtained by Vitousek and Reiners (*Bioscience*, in the press) at Mt Moosilauke.

The evident implication of these data is that low nutrient discharge is a feature of relatively immature ecosystems and that these systems become more leaky on attaining maturity. Nitrogen is a particularly complex element to choose for this type of survey. Not only is its input to an ecosystem complicated by biological fixation, but its output occurs as denitrification and ammonia flux to the atmosphere (see Denmead, Simpson and Freney, *Science*, **185**, 609; 1974) as well as by stream discharge. It is reasonable to assume, however, that as the steady-state ecosystem is approached, the total inputs of the element should be equalled by outputs and this equilibration may well account for Leak and Martin's observed increase in stream nitrate discharge with stand maturity. We may have to wait for a couple of centuries before these suggestions can be confirmed by the controlled experimental techniques of the Hubbard Brook team. □

This Manhattan skyline is a three-dimensional representation of the data from a recent search for charmed particles. A 3.6 GeV/c antiproton beam was used to investigate the interaction $\bar{p}p \rightarrow \bar{K}^0 K^+ \pi^- \pi^- \pi^0$ and blocks are mounted vertically to count mass values of $(\bar{K}^0 \pi^+ \pi^-)$ against the mass

values of $(K^+ \pi^-)$ of which there are two possible combinations giving the x and y horizontal axes. Peaks are evidence for the existence of charmed particles but those that are seen in these results do not tower sufficiently above their surroundings to be convincing—*CERN Courier* (15, 1975).

Solar flares and weather

from John Gribbin

IN *Nature* recently Olson *et al.* (257, 113; 1975) summarised evidence for a link between solar flares and changes in both the geomagnetic index and atmospheric vorticity on Earth. They ended their paper by saying that "we should examine the position of the flare on the disk of the Sun as a factor" in determining the response of weather systems to specific solar events, and in this context a brief communication just published in *Astrophys. space Sci.*, **35**,

L33–L34; 1975, is of topical interest.

In that paper J-T. Horng (Radio Physics Group, Telecommunications Laboratory, Chung-Li, Taiwan) reports a study of the association of geomagnetic events with complex sunspot groups, covering the period 1968–1972. Horng defines a complex sunspot group as one with two or more spots occurring in one penumbra, and has looked only at large geomagnetic disturbances ($A_p \geq 28$). The data include 36 such disturbances associated with 62 visible complete spot groups, and three geomagnetic events for which bad weather prevented any sunspot observations being made. It emerges that there is a

definite association between complex spots which occur between 6.7 and 19.9°E on the solar disk and the occurrence of large geomagnetic disturbances on Earth. The mean displacement of these spot groups, 13.3°E, can be taken as indicating that the spot groups and flares which cause the geomagnetic disturbances are located one day East of the solar meridian, allowing for their usual movement from East to West. For this particular sample, Horng also points out that 59.3% of the events occurred in the solar Northern Hemisphere below latitude 29°N and 40.3% in the Southern Hemisphere below latitude 25°S. But that is hardly surprising since the entire period of the study was close to the most recent solar maximum, when sunspots always form at low latitudes. □

Image processing at Stanford

from Albert Macovski

A meeting on "Image Processing for 2-D and 3-D Reconstruction from Projections: Theory and Practice in Medicine and the Physical Sciences", sponsored by Stanford University Institute for Electronics in Medicine and the Optical Society of America was held at Stanford University on August 4-7.

DUE primarily to the phenomenal success of the EMI brain scanner, the general subject of reconstruction from projections has generated a great deal of interest and enthusiasm. This particular meeting at Stanford, California is the second one of its type, the first taking place last year at the Brookhaven Laboratories.

Although X-ray and γ -ray imaging continue to dominate the scene, a number of novel application areas were presented which use comparable techniques. T. F. Budinger *et al.* (Lawrence Berkeley Laboratory) showed some preliminary results using heavy charged particles rather than X rays. Although the instrumentation is quite extensive, a significant dose reduction is obtained. J. F. Claerbout and P. S. Schultz (Stanford University) showed the application of similar techniques for seismic imaging using the reflections from sonic pulses. A cross-sectional image of the Earth is thus created to aid in activities such as oil exploration. J. F. Greenleaf, *et al.* (Mayo Foundation, Rochester) showed some exciting images of an excised dog's heart made by measuring the time-of-flight of ultrasonic pulses taken at many angles and positions. The reconstructed image

is a cross section representing sonic velocity. A number of other interesting papers were presented on non-radiographic applications including nuclear magnetic resonance zengmatography, electron microscopy, radio-astronomy and plasma diagnosis.

Many papers were devoted to the mathematics of reconstruction, both basic and related to specific applications. There was a strong trend, compared with the Brookhaven Conference, toward the use of direct as compared with iterative reconstruction procedures. In the basic area, R. P. Tewarson (SUNY, Stony Brook, New York) delighted the audience with his very profound fundamental treatment, well sprinkled with humour. He concentrated on methods for reconstructing the difference between the desired image and a standard image which he alluded to as the "average caucasian face." G. T. Herman *et al.* (SUNY, Buffalo), one of the pioneers of the iterative techniques, showed how these techniques converge to the least squares solution. Similarly P. R. Smith (Universitat Basel) along with T. M. Peters *et al.* (Christchurch Hospital, New Zealand) presented a fundamental exposition of the Fourier and back projection methods and the various aliasing considerations. M. Ein-Gal *et al.* (Stanford University) presented a decomposition of the projection data into consistent and inconsistent data and defined a quality factor representing their ratio. This talk invoked a lively discussion between the author, G. T. Herman and R. B. Marr of the Brookhaven Laboratory on the definition of inconsistency. O. J. Tretiak (Drexel Institute) presented an analysis of the point-spread function for direct reconstruction systems. This helped explain many of the artefacts which are being experienced.

In the area of mathematics related to specific applications a few investigators, including S. A. Johnson *et al.* (Mayo Foundation) discussed the problem of bending of rays due to refraction when reconstructions are made using optical or sonic waves. R. Gordon (National Institutes of Health), a pioneer in this field and the organiser of the meeting, presented a novel reconstruction system related to position reconstruction systems. Each event, as received, is assigned its most probable spatial position based on the previous events. A number of papers were presented on optimum reconstructions in the presence of incomplete data. L. R. D'Addario of the National Radio Astronomy Observatory and S. J. Wernecke (Stanford University) each presented papers on maximum entropy reconstructions. These gave impressive results in applications such as radio-astronomy and electron microscopy,

where the acquired data are sparse. A novel Fourier reconstruction system for nuclear medicine was presented by L. T. Chang *et al.* (Lawrence Berkeley Laboratory). A sequence of pinhole images were back projected and filtered in Fourier space to provide the desired reconstruction.

In the areas of improved X-ray and γ -ray reconstructions, the positron ring camera using coincidence techniques appeared quite exciting. L. Eriksson *et al.* (University of California, Los Angeles) and C. J. Thomson *et al.* (Montreal Neurological Institute) showed promising results. A number of papers were given on the problems of polychromatic effects in X-ray reconstruction. A. Macovski *et al.* (Stanford University) illustrated the nature of the distortion and a method of correction. R. E. Alvarez and Macovski (Stanford) showed how the X-ray spectrum could be decomposed so as to delineate density and atomic number effects in the reconstructed image. A similar decomposition based on chemical elements was presented by M. J. Berggren *et al.* (Mayo Foundation). The fan beam configuration which allows simultaneous acquisition of Earth projection received considerable attention. D. P. Boyd (Stanford University) described a fan beam instrument using a xenon detector and P. Stonestrom *et al.* (Stanford University) discussed the scatter problems. The fan beam geometry presents some interesting mathematical reconstruction problems which were treated by R. King (General Electric, Schenectady) and L. Wang and L. H. Cho (University of California, Los Angeles). □

Phonon scattering in solids

from a Correspondent

A conference on "Phonon Scattering in Solids" was held in Nottingham, UK on August 27-30. The proceedings will be published by Plenum Press.

At a good conference one finds out where the ragged ends in our knowledge lie. The conference recently held in Nottingham was no exception as contradictions were exposed by the close proximity of presented papers, and private conversations removed some of the gloss from published articles. But there were plenty of good new experiments reported which stimulated a lot of thought and the new techniques presented make it now possible to work at higher frequencies and with better spectral resolution.

Spectroscopy using phonons rapidly developed from the days of specific heat and simple thermal conductivity measurements when it became clear that there are resonant scattering processes which scatter phonons of well defined frequencies. Systems such as some magnetic ions in crystals, low-lying states in amorphous materials, copper pairs in superconductors, and charge carriers in semiconductors are strongly coupled to phonons and in many cases can only be studied by their interaction with injected phonons.

The two subjects which generated most enthusiastic discussion were predictably the Kapitza problem and amorphous materials. Heat transfer between two different solids, one of which at least is electrically insulating to stop electronic conduction, can be quite reasonably explained in terms of phonons propagating through the interface according to the classical ideas of elastic waves at interfaces as long as it is recognised that the material at the boundary may be somewhat different to the bulk. The way heat transfers from a solid to liquid or solid helium still remains a mystery however, even though the problem is being tackled with a variety of penetrating experiments. There is now little doubt that some of the phonons ($\sim 10\%$) go from the solid to the helium according to continuum theory so that $q_{||}$ is conserved and that the majority of the energy is carried by phonons which inelastically scatter at the interface. It is also clear that these inelastic processes are associated with the first few atomic layers of helium but the nature of these interface states is only speculative. Candidates such as surface waves, desorbed atoms and low energy rotons were hinted at but there was an understandable reluctance for necks to be stuck out too far after 34 years of looking for an answer.

Amorphous materials are in much the same state. Very elegant experiments were reported which indicate that there is a two- or three-level system which is strongly coupled to phonons and photons but whose nature is unknown. This situation is commonplace in high energy physics but in the solid state it is rare and so emphasises how sophisticated our knowledge of crystals really is. It is apparent that the amorphous states have a whole spectrum of relaxation times both to the lattice and to each other. In essentially d.c. experiments such as specific heat, all the states can absorb energy while in dynamic experiments with ultrasound and thermal conductivity only the states strongly coupled to the lattice phonons are seen. Even these states may not be seen if their relaxation time is too long or the ultrasound power too high, as they become saturated and then not

able to scatter. This last effect has been used to measure the time for interchange of energy between states by hole-burning techniques with ultrasound in a similar way to that used in electron paramagnetic resonance for inhomogeneously broadened lines.

A great deal of work is going into magnetic ions which are strongly coupled to the lattice. Many mysteries remain here but one gets the feeling that the subject is bedevilled by samples. There are always too many resonances than can be accounted for but this is not surprising as very dilute impurities can have a large effect and strains as small as 10^{-6} can shift the energy levels. Even the strains due to the dopant being studied are a problem. When positive identifications can be made however, theory seems largely able to cope.

Phonons from superconducting tunnel junctions are being used increasingly to study all those systems with frequencies up to 1 THz. Frequencies an order of magnitude higher were claimed to be generated by shining an infrared laser on to quartz, however these phonons were not measured directly as they were detected bolometrically. It is not clear why this method works but no doubt much more work will be done on this system. Optical Brillouin and X-ray scattering are also being used in complicated experiments to study phonons.

The many other topics discussed at the conference can be read about in the proceedings which it is hoped will be published by the end of the year. There were some 110 papers which indicates the growing enthusiasm for this subject. \square

European astronomy at Leicester

from A. C. Fabian

The first European Conference on Astronomy was held at Leicester, UK on August 12-14.

THE first European Conference on Astronomy recently attracted about 250 astronomers to the hot lecture theatres of Leicester University. At least four orbiting satellites carry European X-ray instrumentation and these provided many of the new results. Radioastronomy was well represented, but there seemed surprisingly little from optical observers.

Transient X-ray sources are the most exciting objects to have been discovered by the Ariel V satellite. Several had been known before the launch of Ariel V last year, but few could have

predicted the large number of bright ones that have now been observed. Estimates seem to indicate one bright transient every 10 days or so, and K. A. Pounds' group at Leicester gave day by day reports on the latest (A0621-00), which is now the brightest X-ray object in the sky. It was speculated that this new source is similar to the binary X-ray sources, and may be associated with accretion on to a white dwarf, neutron star or black hole. This implies a distance less than a kiloparsec or so if the object is not to exceed the Eddington limit for a solar mass object. Above this limit radiation pressure will seriously modify the accretion flow and the result would probably prevent detection of the source. Extrapolation from known X-ray sources would suggest that the optical companion should be visible between about eighth and twelfth magnitude, at most. A better position, to an accuracy of a few arc min should be available and allow for an identification now that the modulation collimators on Ariel V and the American SAS 3 have been pointed in that direction. Spectral changes show a softening of the spectrum as the intensity increased. H. Bradt (Massachusetts Institute of Technology) reported that no periodicities between 0.8 s and 2,000 s were detectable in preliminary data from SAS 3.

Pulsations in the minute range are well known since the discovery of Ariel 1118-61 last December, as recalled by J. G. Ives (Mullard Space Science Laboratory, University College, London). Bradt showed the X-ray "light" curve of A0536+26, a transient source discovered by Ariel V earlier this year near the Crab nebula. A regular dip every 104 s at high energies (>10 keV) degenerates into about six structured dips below about 5 keV. Pulsations of the more constant source, Cen X-3, were shown by I. R. Tuohy (MSSL). He finds a broad double-peaked pulse from the Ariel V data unlike the single pulse that was usually observed from Uhuru. Observations of pulses from Cyg X-1 were reported by G. Auriemma (Frascati). This is remarkable because the pulses, with periods of about 0.083 s were found optically. They represent a significant fraction ($\sim 5\%$) of the optical flux from the system. Only a non-thermal mechanism can radiate so much energy from so small a region.

The recent series of occultations of the Crab nebula, which contains a 33 ms pulsar and was the site of SN1054, have been well covered by X-ray detectors carried on balloons and rockets. F. D. Seward (Lawrence Livermore Laboratory) showed the results of a rocket observation made last November. The moon started occulting the X-ray source soon after

the detectors were locked on, and the signal gradually decayed over the next 150 s or so. Near the end of the flight the detectors were displaced about 10° to take a background reading. A significant drop in count rate was immediately recorded. Seward and his colleagues suggest that this was due to a diffuse source associated with the unoccluded part of the nebula. At a temperature $kT \sim 0.8$ keV and luminosity $\sim 10^{38}$ ergs s^{-1} , this puts at least part of the Crab in line with other X-ray supernova remnants.

Very long baseline interferometry radio observations of the nucleus of NGC1275 (3C84) by E. Preuss (Bonn) and his colleagues contrasted well with the maps shown by A. G. Willis (Leiden) of the large radio galaxies observed from Westerbork. The VLBI observations could be interpreted in terms of a stable map showing 10 components on the scale of ~ 1 milliarc second! (This is about the angle subtended by a man on the moon.) At the other extreme, the large scale emission regions of 3C236 and DA240 could accommodate many Cygnus-As. A compact, highly polarised, and unresolved source has been found at the leading edge of the eastern component of 3C236 which, if not a background source, will be of interest in discriminating between the many theories of radio galaxies.

Many more new and unpublished results and ideas were presented at this very successful conference. In his review of the theory of supernova remnants, S. Gull (Cambridge), showed a memorable radio "photograph" of the supernova remnant Cas A "taken" with the 5 km telescope. The turbulent detail in the shell of this remnant is as dramatic as any optical picture of the Orion nebula. Popular books will never look the same when these new pictures start replacing the old favourites.

The meeting showed that European astronomy is in a healthy state and it is to be hoped that the European Conference on Astronomy may become an annual event. \square

X rays and ion transport in liquids

from Andrew Holmes-Siedle

THE use of photographic film to record X rays has always had the disadvantage that one has to wait to see the image. Another less obvious disadvantage is the "chemical fogging" which impedes perception of fine detail. Direct viewing of fluorescent screens demands high doses to the subject or the use of intensifying systems which, though

costly, do not always give enough detail and do not yield a record of the image in "hard copy". There is now growing interest in a method which seems to combine the virtues of each system with cheapness and simplicity and involves some interesting physics. At least two groups are working on it, using the names 'electron radiography' in the USA and 'ionography' in the UK.

The X-ray shadowgraph image is converted into a charge image on a dielectric by the ionisation of a gas or liquid in a chamber and the transport of the positive ions in a straight line to one wall of that chamber, where they collect as stored charge on a dielectric sheet. This charge image can then be developed with a powder in the same way as in the well-known xerographic processes. The transport of the ions is effected by a fairly high applied electric field and no pre-charging of the sheet is necessary. Such an idea may sound simple but it is only recently that a method yielding a satisfactory resolution has been developed.

Early attempts to use electrostatic image formation all involved the use of pre-charged insulator surfaces. Even before the use of film was established, within months of the discovery of X rays, Righi (*The Electrician*, 37, 75; 1896) had found that X rays would discharge ebonite and that the pattern could be made visible with powders. The discharging of a selenium plate by X rays was embodied in the original Xerox patents but, despite some investigation in the 1950s, "xeroradiography" has not been widely used. Criscuolo (*Non-Destructive Testing*, 14, 28-36; 1956) then found that the X-ray-induced conductivity of air over a charged insulator surface could be used to produce an image but that resolution was still poor, mainly because of the small fraction of photons colliding with gas near the plate. The step to a good image was made by increasing both the atomic number and density of atoms above the insulator and by replacing the field from the charged insulator by an applied field, then simply inserting an uncharged insulator foil between the field electrodes and allowing it to intercept and trap the charged species which drifted towards it. Two groups realised the efficiency of this method at about the same time. H. E. Johns, J. W. Boag and others reported favourable results in 1974 (*Br. J. Radiol.*, 47, 519-529) while A. P. Proudian and others presented a verbal description in 1972 and published results in 1974 (*Radiology*, 110, 667-671).

In both of these publications, the density of atoms near the insulator was increased by using a gas at pressure. Xenon at ten atmospheres proved ideal, since this element has an absorption

peak which nicely matches the white radiation spectrum emitted from a 100-keV X-ray tube. The polarity of field is normally such that the xenon ions bombard and charge the surface of the insulator foil. While the electrons will also produce a charge image, the British workers showed that scattering on the way to the foil caused serious loss of resolution. This team thus used the name ionography for the technique, while the American team preferred to call it electron radiography to avoid the historical associations of the former term.

The American team, Allan *et al.*, have now published (*J. appl. Phys.*, 46, 2766-2767; 1975) details of an improved process, termed "liquid-absorber electron radiography", which avoids the use of gas at high pressure. The extra simplicity of using a liquid transporter medium clearly confers engineering advantages but physicists should also be intrigued by this new requirement for efficient transport of charge in a condensed phase. The composition of the liquid will have to be tailored to meet several unusual demands. Not only must it be a good X-ray absorber but its nature must be such as to minimise recombination and scattering of the ions as they drift to the foil. Of course, in order to reduce lateral charge movement and "fog" from leakage between the field plates, the liquid must also be an excellent insulator when not being irradiated. Since it is desirable to sweep out the ions rapidly, fields near to those producing avalanche effects in the medium will be favoured. Since the science of charge transport in normally non-conducting materials in the condensed phase is still in its infancy, this new demand for know-how may give a welcome increase of interest in the basic processes of transport.

The prediction of the British workers, that a very thin pencil of X rays will produce a spot image of radius about 0.175 mm at half maximum in high-pressure xenon is nicely borne out in their experiments, which indicate an image resolution of about 10 line pairs per mm. The results quoted by the US workers for the liquid medium show a strong improvement on this result, the resolution for the latter medium being much better than 10 line pairs per mm. Clearly, charge image radiography has come of age but should still provide some interesting physical problems during its further maturation. \square

Erratum

In the article 'Jupiter XIII' (*Nature*, 257, 178; 1975) para 2, line 20 should read "magnitude about +22" not "magnitude about +0.22".

A subharmonic lunar tide in the seas off Western Europe

D. E. Cartwright

Institute of Oceanographic Sciences, Bidston Observatory, Birkenhead, UK

A small and often neglected tidal component, which is an exact subharmonic of the M_2 tide, is shown to have unusually large amplitudes over a sea area stretching from Shetland to the Azores, including the North Sea. An explanation is offered in terms of normal oceanic modes recently computed by Platzman, and implications for tidal prediction procedures are discussed.

THE usual picture of the lunar tide-generating potential, a symmetrical oval shape, concentric with the Earth and with its axis directed towards the Moon, is only approximately correct. Because of the finite distance of the Moon the oval is not quite symmetrical, in that the potential on the part of the Earth's surface nearest the Moon is about 1% less than that on the part farthest away. The asymmetry, illustrated in Fig. 1a, produces a daily tidal component which is an exact subharmonic of the principal lunar half-daily tide (M_2), the period of its cycle being a mean lunar day (I ignore the ter-diurnal distortion M_3). This tide is distinct from that normally thought of as the "diurnal tide", and which is due to the monthly excursions of the Moon above and below the Equator. That diurnal tide does not contain a component which is an exact subharmonic of M_2 . If the orbit of the Moon were permanently in the equatorial plane, as in Fig. 1a, there would be no diurnal tides of the usual sort (Fig. 1b), but the subharmonic lunar tide would remain.

The facts set out above are known in tidal theory, but the subharmonic effect is usually neglected in practice because the asymmetry in the generating potential is so small. What is not generally known is that at a number of places, representative of a wide sea area off western Europe, the subharmonic tide actually dominates that part of the spectrum known loosely as the " M_1 tidal constituent". The M_1 group of lines, as it is more properly called, consists of a cluster of harmonic components of the tide-generating potential within 1 or 2 cycles yr^{-1} of 1 cycle per lunar day. It may be split into two distinct groups, one associated with the function

$$\xi^2 P_2^1(\theta) = \xi^2 \frac{3}{2} \sin 2\theta$$

where ξ is the Moon's parallax, and θ is terrestrial colatitude, and the other with

$$\xi^3 P_3^1(\theta) = \xi^3 \frac{3}{2} \sin \theta [(5 \cos^2 \theta) - 1]$$

(P_2^1 is represented in Fig. 1b, and P_3^1 as the broken curve in Fig. 1a). Their spectra are shown in Fig. 2a and b. Since ξ is of

the order $1/60$, the second group tends to have much smaller amplitudes than the first, and this is evident when comparing the logarithmic scales of their spectra. The other distinction is that the P_2^1 group is dominated by two lines at about $1/9$ cycles yr^{-1} on either side of the central frequency 1 cycle per lunar day whereas the P_3^1 group has essentially one strong line at just the central frequency. Figure 2c, d and e shows the corresponding part of the spectra of 18-yr sections of tide gauge records from Newlyn (two sections) and Brest. Lines corresponding to the M_1 group in the potential show up clearly above noise level, and the salient fact is that the 1 cycle per lunar day (subharmonic) line from P_3^1 is the largest of all at both places. This represents a magnification of the P_3^1 lines relative to the P_2^1 lines by a factor of more than 10.

A similar phenomenon had been observed¹ in the analysis of records from Simons Bay, South Africa covering nine years, but there the P_3^1 line dominated on account of an unusual node

Fig. 1 a, Cross section of components of gravitational potential with Moon over the Equator. —, M_2 component. - - - - -, Subharmonic M_1 component (magnified $\times 50$ relative to M_2). b, Form of principal diurnal component with Moon north of the Equator. in the principal diurnal tide at a frequency very close to 1 cycle per lunar day. From further enquiries, it seemed that the subharmonic M_1 tide, as we may call the principal component associated with the P_3^1 harmonic, was first identified in sea level records from Cuxhaven, around 1968 (W. Horn, personal communication). A phenomenon as widespread as Brest, Newlyn and Cuxhaven suggests an oceanic origin, so I searched for other European sea level records of sufficient length for its resolution. The line-separation of $1/9$ cycles yr^{-1} requires 9 yr of records for clear resolution, but 5-6 yr are adequate with special methods², if the noise level is low. Records from Southend covering 18.5 yr recently analysed for other objectives (M. Amin, to be published), was found to have a subharmonic M_1 tide similar to Cuxhaven. Shorter records from the Scilly Isles, Malin Head, Stornoway and Lerwick confirmed its dominance, as at Newlyn, over the entire oceanic coastline of Britain. Another short record, from Dunkerque, gave results similar to Southend.

The results from the places mentioned previously are shown in Table 1. H and G are the amplitude (mm) and Greenwich phase lag (degrees) of the named constituents, and R the amplitude ratio (admittance) to the gravitational potential, in the

normalisation of Cartwright and Tayler³. I have used M_1' to denote the subharmonic tide (in accordance with modern German practice⁴), and M_1 the principal component of the P_2^1 tide, which some⁴ prefer to call "NO₁". The principal lunar semidiurnal tide M_2 is included for comparison. The three entries for Newlyn are for three consecutive 18-yr spans of data, the spectra from two of which are included in Fig. 2; they show the order of variability which may be expected due to noise. There is no obvious relationship between the constants of M_1 , M_1' and M_2 , but the main features described above, large H and R for M_1 , small for M_1' , are clearly supported. One notices that the amplitude ratios for M_1 are about 1-2, which is not very large, but nevertheless comparable with the admittances at M_2 which are generally considered 'large' in the north-east Atlantic. The admittances for M_1' are, however, only of the order of 10^{-1} , which makes their H values small in comparison with those of M_1 . The dominance of M_1 in this area, then, is due not only to magnification of the P_3^1 tide but also to a depression of the common diurnal tide in the Atlantic Ocean as a whole.

The two island stations included at the bottom of Table 1 show that at the distance of the Azores, the dominance of M_1 is reduced to equality in H , whereas as far as Bermuda R become of similar order, and M_1' dominates. The result for Bermuda is, in fact the norm, confirmed at for example Honolulu (19 yr), Venice (12 yr), and Antarctica (9 yr). The phenomenon of a relatively magnified M_1 may well be confined to western European seas (and the vicinity of Simons Bay).

Heuristic explanation

Before proposing a physical cause for the enhanced M_1 or suppressed M_1' tide, it is worth dismissing some possible but implausible suggestions.

(1) Anomalous lines in tidal spectra are often due to nonlinear interactions at sum and difference frequencies. This can indeed affect M_1' , through interaction between N_2 and O_1 , but only noticeably at the shallow water ports of Cuxhaven and Southend. There are no tidal lines of any importance whose frequencies differ by that of M_1 (1 cycle per lunar day).

(2) One might envisage a nonlinear mechanism causing a subharmonic-harmonic instability between M_1 and M_2 . But this would suggest some correlation between the amplitudes of M_1 and M_2 , which is not observed (Table 1). At these places there is nothing anomalous also about the diurnal line K_1 , which is a subharmonic of K_2 .

(3) Some tides are amplified at the resonant frequency of a semi-enclosed basin, as in the Bay of Fundy. But a resonance which selects M_1 and not M_1' implies a tuning width of about 0.1 cycles yr^{-1} ; such fine tuning is unknown in oceanography.

My suggested explanation involves spatial matching of forcing function and normal modes of oscillation, rather than resonance in frequency. Figure 3*a* and *b* shows the wave form of a normal mode of the Atlantic-Indian Ocean system at a period of 23.5 h, computed by Platzman⁶. This is the nearest in frequency to the diurnal tides of many such modes, and can be expected to form an important contribution to the forced tidal wave at 1 cycle per lunar day. Concentrating on the Atlantic, which has the largest wave elevations, one sees an anti-clockwise amphidromic system in mid-northern latitudes and a similar clockwise system in mid-southern latitudes. The arrows indicate the direction of wave propagation at (arbitrarily) 0 hours. At that time in the North Atlantic there is a northbound wave crest with northward currents in the eastern sector, whereas to the west of the amphidrome there is a southbound wave-trough, which also has northwards currents. So at 0 h there are general northward currents in the North Atlantic, and similarly there are general southward currents in the South Atlantic. A quarter of a cycle later there will be generally westward currents in both North and South Atlantic; half a cycle after 0 h, southward currents in the North Atlantic, northward currents in the South Atlantic, and so on. The point is that this pattern of motion matches the rotary motion of the

Table 1 Positions of places analysed, and the amplitudes H (mm), phase lags G (degree), and admittances R of the subharmonic M_1 tide, of the nearby P_2^1 term (M_1), and of the M_2 tide

P_3^1 forcing function, but mis-matches the motion of the P_2^1 forcing function.

The semicircular arrows in Fig. 3c and d represent the azimuth direction of the horizontal stress due to the P_3^1 (left) and P_2^1 (right) components of the Moon's gravitational potential, during a half cycle starting with Greenwich transit (tails of arrows). The direction of rotation reverses across certain latitudes which are drawn. In the wide zones between latitudes 26.5° and 59° the P_3^1 stress rotates in the same sense and phase as the two gyres of the Atlantic in Platzman's model, and with some allowance for change of longitude, the more northwards Indian Ocean gyre is matched also. The matching in the gyre below 60°S is not so good, but on the whole the work done on

this mode of motion by the P_3^1 stress, as measured by the scalar product (stress \times current) integrated over the whole area will be rather high. The P_2^1 stress pattern, on the other hand is much less effective, being northerly in both north and south (below 45°) at 0 h, then westerly in the north Atlantic and easterly in the south, quarter of a cycle later, and so on. The work integral for P_2^1 will be small, and one expects this stress pattern to generate rather weak tides, as observed.

Further support for the importance of Platzman's near-diurnal mode comes from the large amplitudes above latitude 45°N, shown by the numbered broken lines in Fig. 3. The observed amplitudes for M_1 are large in just this area, and do in fact increase towards the north. (The largest amplitudes of

Latitude and longitude scales as in a and b, straight lines mark the latitudes at which sense of rotation reverses.

all, at Cuxhaven and Southend, may be regarded as a displaced product of the tides at the northern entrance to the North sea.) One would expect from Fig. 3 to find still larger amplitudes in north-east Canadian waters, but this has not been investigated. The accuracy of Platzman's model may in any case fall off near its northern boundary.

Implications for tidal prediction

The classical " M_1 tidal constituent" (my M'_1) has always fitted awkwardly into the conventions of "harmonic" prediction, on account of its two major spectral lines separated by 0.23 cycles yr^{-1} , which is too close for resolution from a year's analysis but rather far for an accurate 'slow modulation' scheme. Schureman⁷ devoted three pages to it; Rossiter⁶ included it in a discussion of "troublesome harmonic constituents" and referred to an epistolary dispute about M_1 between Horn and Doodson in 1947. The usual method, which ignores the possible existence of the subharmonic term, takes a nominal frequency of 1 cycle per lunar day ($14^\circ.492 \dots \text{h}^{-1}$) but adjusts with a modulating function whose phase advances from 0 to 360° every 9 yr. Even the definition of the modulating function differs according to authority^{7,8}, so that published constants are valid only if used by the method of the authority which produced them. This odd situation has survived over the years only because the constituent is, after all, rather small, so that errors in prediction arising from it will not be too serious.

The identification of the subharmonic M_1 in the sea area specified confuses the issue still further, and a reappraisal of the whole situation is needed. It is worth mentioning three logical solutions to the difficulty.

(1) One may treat M_1 and the two companion terms of M'_1 as three distinct constituents, each of which has a minor modulating function depending on the lunar 'node', as in common constituents. This is, in fact, the method suggested by the recent DHI tables⁴. To identify these constituents, however, requires several years of data to be analysed, typically 9 yr, or preferably 18 yr.

(2) The "response" method² may be used, which automatically treats P_2^1 , P_3^1 and nonlinear terms separately in an optimum way. This still requires a minimum of 5–6 yr of data to achieve the separation reliably.

(3) If one is restricted to the standard '1-yr analysis' a compromise must be made, depending on the sea area. In areas where the subharmonic M_1 tide has been shown to be normally small, the standard modulation scheme is adequate, although some unification of constants would be desirable. In north-west European seas, I have shown here that one would do best to treat M_1 as a pure subharmonic line, and either ignore M'_1 or infer it from continuity with the more reliable terms O_1 and K_1 from the P_2^1 tide.

I am grateful to Mr R J Tayler and Mrs Anne Edden for assistance with the analysis of the Newlyn data.

Meanders and long waves in the equatorial Atlantic

W. Düing*, P. Hisard†, E. Katz‡, J. Meincke§, L. Miller||, K. V. Moroshkin§§, G. Philander**, A. A. Ribnikov††, K. Voigt‡‡, & R. Weisberg||

Observations from the GATE Equatorial Oceanographic Experiment are presented. They reveal large scale meandering of the westward flowing South Equatorial Current and of the eastward flowing Equatorial Undercurrent with time scales of 2–3 weeks. Meandering of the flow pattern was found to be related to corresponding displacements of the high salinity core of the undercurrent. The observations tend to support the assumption of a long wave propagating westward with a phase speed of 2.3 m s^{-1} and a wavelength of 3,200 km. A possible explanation may be given in terms of unstable waves caused by large scale horizontal shear in the Equatorial Current System.

THE Equatorial Experiment, one of the components of GATE (Atlantic Tropical Experiment of the Global Atmospheric Research Programme, see refs 1–3), was an oceanographic experiment designed to determine the spatial and temporal

scales of transient equatorial phenomena, to study their interaction with equatorial currents, and to investigate the dependence of upper ocean phenomena on atmospheric forcing. The platforms from which measurements were made included stationary and roving ships as well as an array of moored buoys carrying measuring equipment. This experiment culminated during phase II of GATE, from July 27 to August 16, 1974 (see Fig. 1). Complementary observations were made during phase I of GATE, which preceded this project, and phase III, which followed it. Here we report on preliminary results from the Equatorial Experiment and deal mainly with large scale meandering and wave phenomena of the currents within $\pm 50'$ latitude of the equator. Information on these phenomena is based on: (1) current profiling measurements from the research vessels Capricorne (France), A. Dohrn (FRG), A. V. Humboldt (GDR), C. Iselin (USA) and Ak. Kurchatov (USSR); (2) moored current meter arrays positioned by the research vessels Discovery (UK), A. Dohrn, Ak. Kurchatov, Passat (USSR) and Trident (USA); (3) measurements of the temperature and salinity fields from all vessels mentioned above as well as additional measurements from the RV Atlantis II (USA).

The observational techniques in categories (2) and (3) are usual oceanographic procedures, but the observations in category (1) constitute a novel approach (for details on the

profiling current meters (PCMs) and on their mode of operation see refs 4 and 5). The Humboldt used the SRS method⁶ to obtain complementary observations of current profiles.

Meandering of equatorial currents

RV Iselin and RV Humboldt operated in cyclic modes along the western and the eastern trapezoids respectively (Fig. 1). This

procedure made possible the quasisynoptic observations that indicated meandering motions of the flow field as well as of the fields of temperature and salinity at all depths from the surface to well below the core of the Equatorial Undercurrent. Consecutive sections from July 26 to August 16 along 28°W show that the eastward-flowing core of the undercurrent meandered approximately between latitudes 0°50'S and 0°50'N (Fig. 2). Similar sections made by RV Humboldt along 23°30'W confirm that the meridional excursion of the core of the undercurrent occurred within ± 50 miles of the equator. Maximum core displacement took place over a period of 1 week at both, 28°W and 23°30'W. Thus, core displacements at both longitudes occurred on time scales much shorter than previously believed. The jet-like core of the undercurrent displays a pulsating behaviour: the volume transport in the core at 28°W, as obtained by integration within the 20 cm s^{-1} contour (Fig. 2), varied over a range from $4 \times 10^6 \text{ m}^3 \text{ s}^{-1}$ on July 27 to $15 \times 10^6 \text{ m}^3 \text{ s}^{-1}$ on August 5. This feature is also shown in the time-latitude sections in Figs. 3 and 4a, for example, by following the 60 cm s^{-1} isotach in the east-west component in Fig. 3. Pinching of the isotachs occurs around July 30 and around August 16; widening of the isotachs, accompanied by pronounced velocity maxima, occurs around August 7 at 28°W and about 3 d earlier at 23°30'W.

The westward surface flow was unusually strong, although intermittent, throughout the observational period. The westward core of the surface current showed meridional excursions similar to those observed at the level of the undercurrent (Fig. 5). The northerly component at position M2 (Fig. 6) indicates that fluctuations at the surface level at 28°W lag approximately 3–4 d behind changes at the undercurrent level. Such a vertical lag does not seem to occur at 23°30'W. Another phenomenon observed only at the western trapezoid was a

Fig. 3 Time-latitude sections of the flow components at the core level of the undercurrent based on all stations along 28°W and 29°W. Maximum eastward value from each profile was selected at depths varying between 60 and 90 m. Observations by RV Iselin.

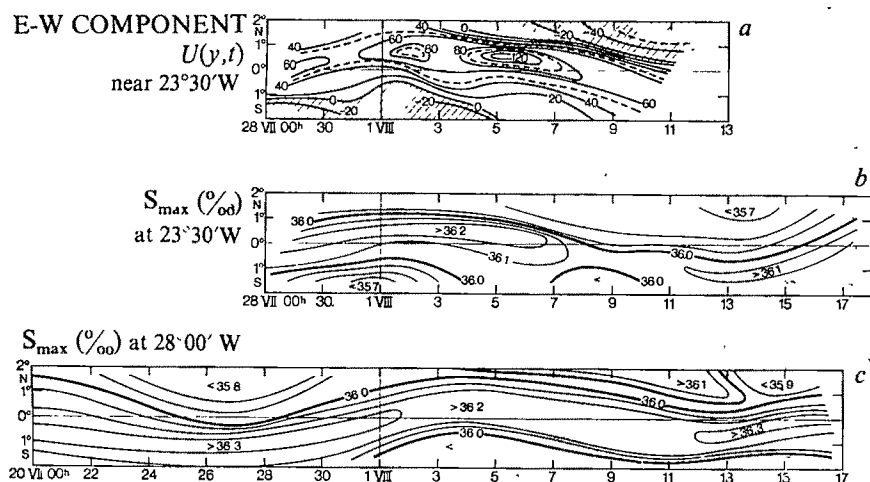

Fig. 4 Time-latitude sections of the east-west current component and of salinity. *a*, Observed by RV Humboldt at 23°30'W; otherwise corresponding to $U(y, t)$ -plot in Fig. 5; *b*, salinity maximum at 23°30'W observed by RV Humboldt; *c*, salinity maximum at 28°W combined from observations by RV Iselin and RV Trident.

surfacing of the undercurrent on August 10 at latitude 1°30'S when weak eastward flow occurred at the surface. By August 15, eastward flow at the surface was observed in the region from 1°30'S to 0°50'S. Remarkably, this happened in spite of prevailing winds from the south-east of about 7 m s⁻¹. This gives the impression that surfacing at 28°W is intrinsically linked to the meandering and wave processes of the equatorial currents.

Comparison of salinity sections (Fig. 4*b, c*) with sections of the eastern component Fig. 4*a* shows that the salinity maximum is a fairly reliable indicator of the meandering of the undercurrent, although the velocity core and the salinity maximum,

data to detect meandering and wave phenomena at other times and locations.

A meander period of about 16 ± 2 d is compatible with all observations presently on hand, including those before phase II of GATE. Corroborating observations were made by RV Kurchatov during phase I at a buoy station at 0°, 23°30'W. Bubnov *et al.*⁷ report results from a series of consecutive temperature casts made between June 28 and July 15, 1974. The temperature variability of the thermocline at the depth of the core of the undercurrent shows a pronounced 8-d periodicity. In conjunction with the dome-shaped temperature

Fig. 5 Time-latitude sections of the flow components at the surface based on all stations along 28°W and 29°W. Values between 0 and 15 m were averaged. Hatched areas denote westward respectively southward flow. Observations by RV Iselin

in most cases, do not occur at the same depth. Usually the salinity maximum is found above the velocity core in the region of strongest vertical current shear. In spite of these differences in vertical structure, horizontal meandering of the undercurrent may be detected from salinity observations alone. For example, salinity sections made during ICITA⁶ at 8°W indicate meandering of the undercurrent with a half period of approximately 14 d, and with meridional excursions of the core to the north and to the south of the equator similar to the excursions observed further to the west during GATE. There is, however, some evidence from the observations by RV Atlantis II that such correlation does not always exist. If the correlation between the salinity field and the flow turns out to be sufficiently reliable, it may be possible to use historical salinity

distribution at the same longitude between 1°30'N and 1°30'S. Bubnov *et al.* conclude that the undercurrent core meandered across the equator with a 16-d period.

Observations by RV Atlantis II at 28°W also fit this picture. Between July 15 and 17, the eastward core of the undercurrent at 28°W was located approximately 44 miles north of the Equator. The observations by RV Iselin (Fig. 3) show the undercurrent to be at its peak northerly excursion at about July 18–20, one-half period before the start of phase II. Furthermore, RV Atlantis II made 17 sections across the undercurrent from 10°W to 33°W before phase II. These observations establish that the undercurrent was frequently displaced off the Equator and also that meandering occurred within 0°50'N and 0°50'S.

Table 1 Eastward and westward propagating waves

Fig. 6 Flow components in the upper layer observed at three fixed levels at $0^{\circ}29'W$ (Position M2) from a surface mooring deployed by RV Dohrn. Smooth line obtained from low pass filtering. Amplitude reduction for lower frequencies due to particular filter response.

Fixed level current meter records made from RV Dohrn during phase II confirm the previously mentioned meander time scales (Fig. 6). A particular feature may, however, be mentioned here since it has important ramifications when interpreting records from fixed level meters. Whereas the northward component shows basically the same long periods as those in Figs 3 and 5, the eastward component at the fixed levels at position M2, at $0^{\circ}29'W$ shows half that period ($\approx 8-9$ d). An apparent doubling with frequency 2ω will occur when a jet-like flow meanders back and forth with frequency ω across a fixed observational point. The representation in Fig 3-5 circumvents this problem.

Wave propagation

A study of the time-latitude distribution of the eastward component at the core level of the undercurrent at $28^{\circ}W$ (Fig. 3) shows a pattern that closely resembles the one observed at $23^{\circ}30'W$ (Fig. 4a). There are three specific features that are strikingly similar in both observations. (1) long period shifting of the undercurrent core across the Equator, (2) appearance of two cell-like maxima in the eastward component, and (3) development of westward flow north of the Equator towards the end of the observation period. The latter observation is confirmed by observations from RV Kurchatov at position P12 (ref. 8). The time-latitude distributions of the salinity maxima at both longitudes (Fig. 4b, c) are independent of the flow field, also show long period meandering of the salinity core and are in good agreement, even in some smaller scale features.

Both flow fields and salinity fields at the two longitudes which are separated by 500 km reveal that the pattern at $28^{\circ}W$ lags several days behind that at $23^{\circ}30'W$. Combining all information now available gives a lag estimate of $\Delta T \approx 72 \pm 7$ h. Using this information, simple geometric reasoning gives eastward or westward propagating waves according to Table 1. Thus, there are basically two alternatives: (1) very long westward moving waves, or (2) much shorter, westward or eastward moving waves. It turns out that the PCM observations from the eastern and western trapezoid (Fig. 1) support the assumption of a long westward propagating wave (S. A. Thorpe, personal communication) with $L = 2,600 \pm 390$ km and $c = 1.9 \pm 0.3$ m s $^{-1}$. Phase relationships between $28^{\circ}W$ longitude (positions P6 to P10) and $29^{\circ}W$ (positions M1 to M3) longitude were not sufficiently convincing to justify an interpretation in terms of short eastward (or westward) moving waves. A final determination of phase propagation in the various frequency bands is

expected to be forthcoming from current meter records of longer duration.

Observations made by RV Capricorne at $10^{\circ}W$ were carried out over a relatively short period, from July 30 until August 10; meridional station spacing was 60 miles, and resolution is therefore limited. A detailed comparison and phase alignment with the observations further to the west is therefore not possible. There is no doubt, however, that large scale meandering also occurs at this longitude. During phase II of GATE, the northward component of the flow was predominantly positive at the level of the undercurrent with values $v \approx 40 \pm 18$ cm s $^{-1}$, whereas the eastward component was $u = 85 \pm 19$ cm s $^{-1}$. This is in contrast to a sequence of 18 current profiles observed at 3-hourly intervals at $10^{\circ}W$ during August 1973 (ref. 5). At that time the mean value v was southward, $v \approx -42 \pm 12$ cm s $^{-1}$, at the level of the undercurrent, whereas $u \approx 55 \pm 15$ cm s $^{-1}$; that is, during both years, 1974 and 1973, the undercurrent veered between 25° and 35° northward or southward respectively from its course due east.

Concluding the observational part, we note that the 16-day wave or meander is the dominant feature in the surface layer

Fig. 7 Low pass filtered current vectors at three fixed levels below the core of the undercurrent at $0^{\circ}28'11'W$ (Position K2) from a subsurface mooring positioned by RV Trident.

and in the core level of the undercurrent. Additional observations by Meincke⁹, as well as those from a subsurface instrumented mooring positioned by RV Trident, clearly show that a 16-d wave is not a predominant feature at depths below 200 m. As shown in Fig. 7, the predominant oscillations are of both shorter and longer periodicities; of the order of 3–4 d and of the order of 1 month. These oscillations are coherent between 28°W and 26°W.

Probable cause of meanders

Cross-equatorial winds may displace¹¹ the core of the undercurrent from the Equator. An abrupt change in the winds could thus cause the undercurrent to meander across the Equator while it adjusts to the new wind field. It is, however, improbable that the meanders described (here) were generated in this manner because vessels on the equator on all longitudes from 10°W to 29°W found the winds to be remarkably steady throughout GATE.

A preliminary analysis (G. Philander, unpublished) of the stability properties of the equatorial currents reveals that the Equatorial Undercurrent was stable during GATE, but that the surface currents—the westward South Equatorial Current at and south of the equator, and the eastward North Equatorial Countercurrent to the north—had sufficient latitudinal shear to be inertially unstable. The curvature of the earth (β -effect) and equatorial divergence can both destabilise this current

system. The westward propagating unstable waves are predicted to have a wavelength of about 2,000 km, a period between two and three weeks, and an e-folding time of about one month. These numbers and the predicted phase lag between disturbances in the surface layers and those at greater depths are in reasonable agreement with the measurements described earlier.

If the surface currents are indeed unstable then the meander of the undercurrent at the equator is only part of a phenomenon with a much larger latitudinal scale. Furthermore, waves with a wavelength in excess of 2,000 km in an ocean basin which, at the equator, is barely 5,000 km wide, are likely to excite other modes of oscillation. Further analysis of the GATE data should provide answers and could potentially change our present view of the generating mechanism.

Note added in proof: Additional observations supplied by Dr V. A. Bubnov show that oscillations with comparable amplitude and period also occurred during phases I and III of GATE.

Measurements of environmental γ radiation levels on Eniwetok Atoll were combined with pertinent population distributions and expected future life styles to assess the external doses that could be received by the Marshallese people on their return to the former US nuclear weapons test site in the Pacific.

WITH the prospect of habitation in the near future, a comprehensive survey of the total radiological environment of the Eniwetok Atoll was undertaken to provide a basis for determining whether or not the atoll can be safely rehhabited by the former Marshallese population¹. As an integral part of the total radiological survey plan, a study was made to assess the total external dose that the returning population might receive as a result of the radiological contamination distributed in the environs of the atoll. Eniwetok Atoll was one of the US nuclear weapons testing sites in the Pacific, and is situated in the northern part of Micronesia in the Central Pacific Ocean about 3,800 km south-west of Honolulu. The atoll consists of 40 islands on an elliptical coral reef surrounding a lagoon with major and minor axes dimensions of 37 and 27 km, respectively.

The islands, which were given male and female code names during the US occupancy, are shown in Fig. 1. The total land area is about 7 km² with the land height generally averaging 3–5 m above mean sea level. The islands vary in size from small sand bars of a few hundred square metres to heavily vegetated islands of about 1.5 km². The largest islands, and therefore those of most importance for future habitation, are Fred, Elmer and David in the southern part and Janet in the northern part of the atoll.

A total of 43 nuclear tests took place during the 1948–58 testing period. Most of the tests were conducted throughout the northern part of the atoll. Slightly over half of the nuclear devices were detonated over the lagoon and ocean areas whereas the remainder were detonated on several of the northern islands. As a consequence, the major radiological impact of the testing programme occurred throughout the northern islands with only minor radioactive contamination on the southern islands.

Since the external dose is almost entirely the result of γ -emitting radionuclides, with only minor contributions from α and β emitters, it was essential to obtain the best possible description of the geographical variability of the γ exposure rates in air on each island. The following is a brief description

Fig. 1 Map of Eniwetok Atoll.

of the techniques used to measure these exposure rates and how the resulting data, in conjunction with pertinent population statistics and expected life style, enabled us to make realistic estimates of the external dose to future inhabitants.

Measurement techniques

Several independent techniques were used to measure these exposure rates since each technique has its own set of limitations (for example, nonlinear energy response, portability of equipment, and extent of geographical coverage). We used results from the following techniques to determine the total exposure rates at 1 m above the ground: (1) portable, hand-held NaI scintillation detector measurements at 1,000 locations distributed over all islands, (2) LiF and CaF_2 : Dy thermoluminescent (TLD) measurements at 100 locations on selected islands, and (3) a helicopter-borne array of 40 NaI crystal spectrometers flown in a grid pattern over each island. The third technique reveals that the primary contribution to the total exposure rates was caused by ^{137}Cs and ^{60}Co activities in the soil. Soil γ spectral measurements indicate that trace amounts of other γ emitters such as ^{125}Sb , ^{155}Eu , and ^{241}Am contribute at most 3–5% of the total exposure rate¹ and, therefore, were omitted in the dose evaluation.

Because of its energy linearity, excellent thermal stability and approximate air equivalency for a typical environmental

radiation field, we selected the LiF results as the reference to which measurements obtained by the other techniques could be compared. This comparison revealed that the LiF measurements are 17% less than those of CaF_2 . This is reasonable in view of the enhanced energy response of the CaF_2 at low energies. Most importantly, however, the aerial survey and the portable NaI detector results agree, on average, within 10% with the LiF measurements. This is within the accuracy of the measurements, and the agreement is considered excellent.

As expected, the highest exposure rates were measured on the northern islands. The highest average value of $115 \mu\text{r. h}^{-1}$ was recorded on Belle. The remaining islands typically have exposure rates of $10\text{--}80 \mu\text{r. h}^{-1}$. In general, the highest levels were found at centres of the island or in proximity to ground zero sites, and were usually related in a direct way to the vegetation density in the immediate area. The southern islands are characterised by uniformly distributed levels of less than $1 \mu\text{r. h}^{-1}$ (see ref. 1 for full details of data).

External dose determination

In addition to the γ -ray exposure rates, the expected living patterns of the future inhabitants must be considered to evaluate the external dose problem. Because of the uncertainties inherent in predicting future living patterns, several cases were

†Southern islands include all islands from Tom to Leroy proceeding clockwise around the atoll.

chosen for analysis (Table 1). The selection was based on the most recent information available regarding present population figures, age distributions, and expected life styles¹. Furthermore, the cases were chosen in such a way as to bracket the most likely range of doses that could be received by any sizeable segment of the population (a total of 430 people). This will enable any other reasonable pattern to be inferred by proper interpolation of the results obtained for the cases shown in Table 1.

The cases are based on the assumption that some fraction of the population may choose to reside primarily on Janet (the largest island within the northern part of the atoll), with the remainder residing on Fred, Elmer, or David in the southern group of islands. Each case considered allows for visits to other islands. Case Ib differs from case Ia in that more time is allotted to temporary occupation of islands other than Janet at the expense of less time being spent in the Janet village area. These cases, or combinations thereof, are considered to represent the most likely living patterns.

Even though wide variations in γ -ray exposure rates were measured throughout the northern islands, it was necessary, for the purpose of calculating the dose, to derive the most reasonable values of the current mean exposure rates for each specific geographical area considered. These values are shown in Table 2. The mean exposure rates for specific areas of Janet were obtained by examination of the ^{137}Cs and ^{60}Co isoexposure-rate contour maps provided by the aerial survey. The village area was assumed to lie along the lagoon side of the island. The mean values given for all of the northern islands were obtained by weighting the mean exposure rates for each individual island with the area of each island. Since the minor contamination of the southern islands is relatively uniform, the mean ^{137}Cs and ^{60}Co exposure rates were chosen by inspection of the individual aerial-survey contour maps. The cosmic-ray contribution was estimated to be $3.3 \mu\text{r. h}^{-1}$ at this latitude (11°N) and the naturally occurring radionuclides in the soil and seawater were expected to contribute an additional $0.2 \mu\text{r. h}^{-1}$.

Integral 5, 10, 30 and 70-yr γ -ray doses for each age group were calculated for each case or living pattern described in Table 1. The results were then combined with the present population distribution, which is also shown in Table 1. Corrections were made for radioactive decay, but not for

possible weathering and subsequent deeper penetration of the radionuclides in the soil. The results of these calculations are given in Table 3 and are labelled 'unmodified.' Additional calculations were made to ascertain the effect of reasonable attempts to reduce the exposure rates on the atoll.

The first modification, labelled 'village gravelled' in Table 3, reflects the effect of covering the village areas with about 5 cm of uncontaminated coral gravel—a common practice throughout Micronesia. This action can be expected to reduce the γ -exposure rates in the village area by approximately a factor of 2. The second and third modifications are based on the assumption that clearing the islands for agricultural use and housing will result in some mixing of the topsoil. It seems that it would be practical during this period to also plough many of the more contaminated islands to a depth of 30 cm. Assuming that ploughing results in mixing rather than burying the topsoil, an average reduction in exposure rates of about a factor of 3 may be obtained. This is based on the present 3–5-cm relaxation lengths (the depth at which the activity is e^{-1} , or 37%, of the surface activity) for activity depth distribution in the uppermost soil layers of the more contaminated areas. This value, however, is highly variable from site to site. In Table 3, modification 2 indicates the effect of ploughing only Janet, whereas modification 3 reflects the additional effect of ploughing all the northern islands. Deeper ploughing

Table 2 Estimated mean exposure rates ($\mu\text{r. h}^{-1}$) used for dose calculations

Major geographical area	Source	Village	Interior	Beach

3. + all northern islands ploughed	(0.24)	(0.45)	(1.17)	(2.41)
Sea level USA (80 mrad yr ⁻¹) typical	0.40	0.80	2.40	5.60

or turning over the soil rather than mixing it would, of course, result in even greater reductions in exposure rate. For example, mixing to a depth of 60 cm would reduce the exposure rates by an additional factor of 2, whereas covering the sources with approximately 30 cm of uncontaminated soil would essentially reduce the exposure rates to negligible values similar to those observed on the southern islands. Removing the top 15 cm of soil, which often contains about two-thirds of the activity, would result in a threefold reduction in the exposure rates. The advantages of ploughing or removing the topsoil should, however, be considered on a case-by-case

basis because of the highly variable distributions of activity with depth.

From Table 3 it can be seen that extensive modifications may not be required to reduce the dose levels to values comparable to typical US values². Keeping in mind that the selected cases represent approximations to the most likely living patterns, one observes that even for cases Ia and Ib, the unmodified 70-yr integral doses are comparable to the US values, although cases II and IV lead to considerably lower doses. The mean integrated doses shown in Table 3 were derived by averaging those for cases Ib, II, III and IV. This implies that half the returning population live on Janet and the other half live on Fred, Elmer or David and that trips to the northern or southern islands are equally likely for both groups. The unmodified mean population doses are all quite comparable with US values. At most, implementation of modifications 1 and 2 should be enough to assure mean population exposures well below the US levels.

Because of the low amount of natural radioactivity normally present in the coral atolls, the external dose levels calculated for cases I-III are still appreciably higher than corresponding levels found elsewhere in the Marshall Islands (essentially case IV). The results for cases II and IV indicate that restricting the permanent villages to 'clean' southern islands at least temporarily would result in lower exposures.

All of the doses discussed so far result from free-air γ -ray plus cosmic-ray exposures. The effect of shielding by structures or the body itself on gonadal or bone doses has been ignored. To convert from free-air dose (rads) to gonadal dose (rem), a body-shielding factor of 0.8 may be used³.

Demonstration and origin of six tertiary base pair resonances in the NMR spectrum of *E. coli* tRNA^{Val}₁

Brian R. Reid

Biochemistry Department, University of California, Riverside, California 92502

George T. Robillard

Department of Physical Chemistry, University of Groningen, Groningen, The Netherlands

The 360-MHz NMR spectrum of E. coli tRNA^{Val}₁ reveals 26 resonances, six of which are derived from tertiary base pairs. The origin of these tertiary resonances and their approximate positions in the spectrum are discussed in relation to the crystal structure of tRNA.

EACH Watson-Crick base pair generates a single low field nuclear magnetic resonance (NMR) derived from the ring NH hydrogen bond¹. Kearns *et al.*^{2,3} showed that the ring NH hydrogen bonds from base pairs in tRNA in H₂O solutions, although solvent-exchangeable, possessed

adequately long helix lifetimes to generate discrete resonances with chemical shifts in the -11 p.p.m. to -15 p.p.m. region. High resolution NMR studies of several class I tRNA species (20±1 cloverleaf base pairs) have been carried out; the spectra were interpreted to contain 20±1 low field resonances from secondary base pairs, that is it was claimed or assumed that no extra resonances from tertiary base pairs were present²⁻¹⁴.

We recently showed that, of all the class I tRNA species so far studied, *Escherichia coli* tRNA^{Val}₁ exhibited the best-resolved low field NMR spectrum; integration of the 270-MHz spectrum of this tRNA on the assumption that several resolved peaks contained a single proton, indicated

Fig. 1 360-MHz spectrum of *E. coli* tRNA₁^{Val} in the presence (a) and absence (b) of magnesium. The solvent for the upper spectrum was 10 mM Na cacodylate, 15 mM MgCl₂, 0.1 M NaCl, 1 mM EDTA, pH 7.0. The solvent for the lower spectrum was 10 mM Na cacodylate, 10 mM EDTA, pH 7.0. In both samples the tRNA concentration was approximately 25 mg ml⁻¹ (about 1 mM) and the spectra were signal averaged for several hours to improve signal-to-noise ratio.

that, contrary to previous interpretations, the spectrum contained several extra resonances derived from tertiary base pairs¹⁵. We have now reinvestigated *E. coli* tRNA₁^{Val} at 360 MHz; the improved resolution reveals six tertiary base pairs in the solution structure of this tRNA. The demonstration of 26 ± 1 base pairs is independently corroborated by calibrating the intensity of the low field spectrum with respect to the intensity of the methyl resonances of the three methylated bases in the molecule.

Internal calibration of 360-MHz spectrum

E. coli tRNA₁^{Val} was purified to 98% homogeneity by standard chromatographic procedures. Figure 1 shows the 360-MHz spectrum at 35 °C; in the presence of Mg²⁺ (Mg²⁺-tRNA ratio of 15) and in the absence of magnesium. In the magnesium-containing spectrum there are 16 resolved peaks between -11 p.p.m. and -15 p.p.m. In our previous spectra at 270 MHz we were able to integrate

with respect to the single proton peaks at -14.9 p.p.m. and -14.3 p.p.m. and establish that the total intensity corresponded to 26 ± 3 protons. Now, with the superior resolution at 360 MHz, we can integrate most peaks individually. Peaks A, B, E, F, M, N, O, P have the same intensity which we assume to correspond to one proton. Based on this assumption peaks C, D, K and peak H+I correspond (with an error of less than 10%) to two protons. Peak J contains three protons and peak G contains five protons, peak L corresponds to an intensity significantly greater than two protons. The experimental peak intensities and their nearest integral values are listed in Table 1. Thus integration of resolved individual peaks enables us to determine the overall intensity with much greater accuracy and leads to a value of 26 ± 1 protons. Since there are only 20 secondary base pairs in this tRNA (Fig. 3) this establishes that there are at least six tertiary base pairs involving ring N · · · H bonds in the solution structure.

Table 1 Integrated intensities of individual peaks in the 360 MHz spectrum of *E. coli* tRNA₁^{Val}

Peak	Position (p.p.m.)	Intensity	Integral value
A	-14.9	0.8	1
B	-14.3	1.0	1
C	-13.8	2.0	2
D	-13.7	2.1	2
E, F	-13.5, -13.4	1.9	2

N	-11.8	0.9	1
O	-11.5	0.9	1
P	-11.3	0.9	1
Total			26 ± 1

Independent calibration based on methyl resonance intensity

The validity of the assumption that the resolved small peaks in Fig. 1 contain one proton can be justified on the grounds that, if they contained two protons the spectrum would indicate 54 base pairs which is impossible with only 76 nucleotides. Since the conclusion that six resonances from tertiary base pairs were present in the spectrum is, however, contrary to all previous interpretations of class I tRNA spectra, we felt it was important to calibrate independently the intensity of a single proton.

A sample of 11 mg of *E. coli* tRNA₁^{Val} was dissolved in 2.1 ml of water and two samples of 1.00 ml were lyophilised in separate small tubes. The first sample was dissolved in 0.20 ml of D₂O and the high field spectrum in the methyl region was taken; the second sample was dissolved in 0.20 ml of the normal H₂O buffer and the low field spectrum taken as usual. Both spectra were accumulated

for the same number of sweeps at the same r.f. power. Figure 2 shows the two spectra. There are three resolved peaks of equal intensity at -2.8 p.p.m., -2.6 p.p.m. and -1.1 p.p.m. in the region expected for methyl resonances. Figure 3 shows the cloverleaf structure of *E. coli* tRNA_I^{Val} which contains three methylated bases, namely m⁶A37, m⁷G46 and rT54. Thus the three methyl peaks in the high field spectrum define the intensity of three protons at the same spectrometer settings used in the low field spectrum. Peaks A, B, M, N, O, P all have an intensity between 30% and 35% of the methyl intensity, thus establishing unequivocally that they are in fact single protons. Furthermore, the overall intensity of the low field spectrum is 8.5 times the methyl resonance intensity, again corroborating the presence of 26 ± 1 base pairs.

Previous assignments of methyl resonances in tRNA by Kan *et al.*¹⁶ enable us to assign the peak at -1.1 p.p.m. to rT54. The peaks at -2.8 p.p.m. and -2.6 p.p.m. must be m⁷G46 and m⁶A37 and, based on the data of Kan *et al.*¹⁶, the -2.8 p.p.m. peak can be tentatively assigned to m⁷G46. The peak at -1.2 p.p.m. has an intensity of approximately 2 protons and is probably the methylene protons of the oxyacetic side chain of residue V34 in the wobble position of the anticodon triplet. The peak at -0.2 p.p.m. is a solvent contaminant, but there is still some rather diffuse intensity between -0.7 p.p.m. and -2.5 p.p.m. which may be derived from hU17.

Base pairs contributing tertiary resonances

The crystal structure of yeast tRNA^{Pho} has been determined at 3 Å resolution^{17,18}. The fact that almost all

positions involved in tertiary bonding in yeast tRNA^{Pho} are occupied by the same nucleotide in *E. coli* tRNA_I^{Val}, together with more detailed arguments on the general structure of class I tRNAs^{19,20}, prompted us to consider the origin of the tertiary base pair resonances on the basis of the crystallographic data. The five known tertiary interactions involving ring NH hydrogen bonds are shown in Fig. 4. Four of these involve ring NH...ring N bonds and one (G15-C48) involves a ring NH which bonds to an exocyclic carbonyl oxygen; hydrogen bonding to carbonyl oxygens is less deshielding and would be expected to generate a ring NH resonance towards the high field end of the -11 to -15 p.p.m. region¹. There are nine tertiary interactions seen in the crystal structure^{17,18}; however, three of them (A9 to AU12; A21 to A14; G26 to A44 or A26 to G44 in tRNA_I^{Val}); involve exocyclic amino hydrogen bonds instead of ring NH bonds and thus would not be expected to contribute to the -11 to -15 p.p.m. region of the spectrum¹. The last tertiary pair is G18-ψ55. The precise bonding in this interaction has not been determined unambiguously; however, recent data (A. Rich, personal communication) indicate that it involves a ring NH proton which probably bonds to a ribose oxygen. Such bonding would lead to a tertiary resonance which would also be expected to be towards the high field end of the -11 to -15 p.p.m. region of the spectrum. The crystallographic data showing five definite and one probable tertiary interaction involving ring NH bonds, and the data presented here showing six tertiary ring NH resonances, are in excellent agreement. Our data are completely consistent with the crystal structure being the actual structure in solution.

Fig. 2 Low field hydrogen bond and high methyl spectra of *E. coli* tRNA_I^{Val} samples at identical concentrations. Duplicate samples (26.2 mg ml^{-1}) were prepared as described in the text in D₂O containing 15 mM MgCl₂, 0.1 M NaCl (lower spectrum) and in 10 mM cacodylate, 15 mM MgCl₂, 0.1 M NaCl, 1 mM EDTA, pH 7.0, H₂O buffer (upper spectrum). Both spectra were accumulated at the same r.f. power for 1,500 sweeps of 16 s each at a temperature of 38 °C.

Fig. 3 The cloverleaf structure of *E. coli* tRNA₁^{Val} as reported by Yaniv and Barrell²³ and by Kimura *et al.*²⁴.

Expected chemical shifts for tertiary resonances

The environment of the various tertiary base pairs in the crystal structure, together with the approximate ring current shift contributions from neighbouring bases determined previously³, can now be used to estimate the approximate position of these tertiary resonances. The s⁴U8-A14 tertiary interaction has been assigned to peak A at -14.9 p.p.m. by chemical modification with cyanogen bromide¹³, additional modifications of this unique sulphur in *E. coli* tRNA₁^{Val} and *E. coli* tRNA₁^{Arg} by Wong *et al.*²¹ agree with this assignment. The reason for the extreme low field position of this tertiary resonance is the inherently

greater deshielding of the ring NH of s⁴U compared with U.

The T54-A58 interaction involves a ring NH...ring N bond. It is stacked with G18-ψ55 on one side and with G53-C61 on the other side; hence this resonance will be only moderately upfield shifted by neighbouring ring current effects. Since AT pairs have similar resonance positions to AU pairs²², we would expect the T54-A58 resonance to be somewhere in the -13.5 to -14 p.p.m. region, that is peaks C, D, E or F (peak B is in the position expected for the secondary AU6 pair).

The G19-C56 interaction is a standard Watson-Crick pair with a ring NH...ring N bond. This tertiary pair is interesting in that it constitutes one extremity of the molecule with no residue on one side and G57 stacked on the other side. Thus, this resonance would be only moderately shifted from -13.6 p.p.m. to somewhere in the -12.7 to -13.3 p.p.m. range, that is peak G, H or I.

The m⁷G46 to G22 tertiary interaction is a ring NH bond from m⁷G46 to the ring N of G22. Its environment involves stacking with A21, A14, A9 and A23¹⁹. Since adenine is the most potent ring current shift base³, this resonance would suffer an extremely large upfield shift—perhaps 2 p.p.m. or more. Thus the 46-22 tertiary resonance would be expected in the -11 to -12 p.p.m. region (peak M, N, O or P).

The 15-48 and 18-55 tertiary interactions involve ring NH protons which do not bond to ring nitrogens but instead bond to oxygen atoms. Such bonding has been shown to be less deshielding¹ and in addition these bonds would suffer an average upfield ring current shift from their stacking neighbours¹⁹. Thus the 15-48 and 18-55 resonances would be expected at the high field end of the spectrum between -11 and -12 p.p.m., that is peak M, N, O or P.

To summarise, the 8-14 interaction is at -14.9 p.p.m. and the 54-58 and 19-56 interactions are probably around -13.7 p.p.m. and around -13.0 p.p.m. respectively. The crystallographic data also lead us to predict that the three remaining tertiary resonances—15-48, 18-55 and 46-22—will all be in the -11 to -12 p.p.m. region, the spectrum reveals four protons in this region and the secondary pair G5-C68 is predicted to be at -11.6 p.p.m.

Tertiary structure in absence of magnesium

The low spectrum in Fig. 1 is that of a sample dialysed for 48 h against three changes (61 each) of double distilled water, lyophilised, and then dissolved in 10 mM sodium cacodylate, 10 mM sodium-EDTA, pH 7.0, at a concentration of 1 mM tRNA. The sodium ion concentration in the

Fig. 4 Tertiary hydrogen bonding interactions seen in the crystal structure of yeast tRNA^{Phe} determined by Kim *et al.*^{17,19} and by Robertus *et al.*¹⁸ and Klug *et al.*²⁰. Only interactions involving ring NH hydrogen bonds are shown and these are denoted in bold face.

added solvent is 40 ± 5 mM. The lyophilised tRNA is the sodium salt and, at 1 mM, would generate another 75 ± 5 mM sodium ion. This excess EDTA-no magnesium solvent was chosen in the hope of destabilising tRNA tertiary structure. The 35 °C (and also the 45 °C) spectrum revealed, however, that all 26 resonances are still present. There are only two resonances which shift slightly in the non-magnesium structure, peak E (-13.5 p.p.m.) shifts downfield slightly into peak D, and peak I (-12.7 p.p.m.) shifts upfield slightly into peak J. Although it is difficult to interpret unambiguously such a subtle change, our current hypothesis is that the stacking of the acceptor helix on the rT helix (base pair 7 on base pair 49) is changed from the imperfect 17° stack¹⁷ to a more colinear stack. Concomitant with this change is a noticeable sharpening of the resonance at -10.4 p.p.m. We have assigned this resonance to the secondary G50-U64 pair¹⁵ which is presumably more protected from solvent exchange in the new structure.

The major conclusion to be drawn from these two spectra, however, is that all the tertiary interactions are formed even in the absence of magnesium; in fact the lack of spectral changes in all the other resonances suggests that the non-magnesium structure is remarkably similar to the magnesium-stabilised structure. Stabilisation of the structure by traces of residual bound magnesium can be discounted since heating the 1 mM tRNA sample in 10 mM EDTA to 65 °C for 1 h followed by subsequent cooling to 35 °C, resulted in a spectrum identical to the lower spectrum in Fig. 1.

Relation to earlier tRNA NMR data

We have now shown that *E. coli* tRNA_I^{Val}, with 20 secondary base pairs, contains six tertiary base pair resonances in its low field NMR spectrum; do the other class I tRNAs studied previously really have no tertiary resonances as claimed, or have their spectra been misinterpreted? The spectrum of yeast tRNA^{Phe} has been studied in greatest detail and has assumed the role of a 'reference spectrum'^{2-6,8-12}. The integration of low field spectra has been complicated by the lack of suitable internal standards with such large chemical shifts. Using Met-cyanomyoglobin as an external standard Wong *et al.*⁴, after normalising the two spectra to the same molar concentrations and the same number of accumulated sweeps, arrived at an intensity of 18.6 protons in the total spectrum. A composite peak at -13.7 p.p.m. was found to contain slightly more than three protons; this peak was normalised to 3.00 protons and subsequently became an 'internal stan-

dard'. A more recent revision by Kearns *et al.*¹⁰ reported a value of 19.7 protons for the total intensity of the yeast tRNA^{Phe} spectrum, but again made the assumption that the -13.7 p.p.m. peak contained three protons. We have re-examined the low field spectrum of yeast tRNA^{Phe} at 360 MHz (manuscript in preparation). At this resolution the peak at -13.7 p.p.m. resolves into three peaks of intensity 1:2:1, that is it contains four protons. Since this peak has previously been assumed to contain three protons and was used as an internal standard, it follows that the true intensity should be 1.33 times higher than reported. We note that 1.33 times 19.7 is in fact very close to 26. Independent integration of the yeast tRNA^{Phe} 360-MHz spectrum, which resolves into 14 peaks instead of the nine peaks in the 300-MHz spectrum, leads to a value of 26 ± 1 protons. Thus, we believe that all class I tRNAs probably contain approximately six tertiary resonances in their low field spectra, and previous NMR analyses have been erroneously interpreted.

We thank Susan Ribeiro and Lillian McCollum for technical assistance. This work was supported by grants from the US Public Health Service and the US National Science Foundation to B.R.R. The use of the Dutch NMR facility at the University of Groningen and the support of the Netherlands ZWO is acknowledged.

letters to nature

X-ray outburst from the direction of the galactic centre

WHEN the Uhuru satellite examined the X-ray emission from the region of the galactic centre in 1971 an extended region of emission centred on the radio source Sgr A and about 2° in extent was observed¹. We report here details of a transient point X-ray source, A1742-28, which has been observed at the centre of this region by the Ariel V rotation modulation collimator (RMC) experiment. Its rise to a peak and subsequent decline by a factor of two over 12 d were monitored. The

position was found to be $\alpha = 17^{\text{h}} 42^{\text{m}} 26.0 \pm 4.8^{\text{s}}$, $\delta = -28^{\circ} 59.8 \pm 1.2'$ (1950.0 coordinates, 90% confidence limits).

Figure 1 shows the intensity variation of the new source. Observations were made primarily in the photon energy range 3.0 to 7.5 keV although some data were obtained in the range 4.6-12 keV. Each plotted point represents observations spread over a period of one orbit (101 min). The RMC experiment is primarily designed to measure positions of point sources and has a grid pitch to separation ratio of 112, corresponding to an image response with full width at half maximum (FWHM) of

Fig. 1 The X-ray light curve of the transient A1742-28.

15' for a point source². Thus, we expect little or no response to extended sources larger than this and the intensities plotted correspond entirely to the new point source. The method of analysis occasionally leads to relatively large errors in intensity in regions as complex as that around the galactic centre where several other sources are always within the 17° FWHM field of view of the experiment. Thus, we do not consider the occasional large deviations from a smooth curve as necessarily significant.

In Fig. 1 the data points in the higher energy mode have been approximately normalised to bring them on to the same curve as the rest of the observations. This normalisation factor, together with the crude three-channel pulse height information available within each energy band have been used to deduce an approximate spectrum. Our findings are in reasonable agreement with those of J. C. Ives (personal communication) who reports a power law spectrum with a photon number index of about -3 and N_H approximately $2 \times 10^{23} \text{ cm}^{-2}$.

For comparison with counting rates quoted in the Uhuru (3U) catalog our figures should be multiplied by about 13. At the peak of about 170 counts s^{-1} the observed flux is about $4 \times 10^{-8} \text{ erg s}^{-1} \text{ cm}^{-2}$ in the energy range 3–10 keV.

Observations by another experiment on the same satellite indicate that the source was not present at comparable intensity

96 d before our observations commenced (K. Pounds, personal communication). No data are available for the period after March 1.

We have determined the coordinates of the new source using nearby X-ray sources of accurately known positions as standards. Lunar occultation positions for GX5-1 and GX3+1 are available^{3,4} and the positions of GX349+2 and GX9+1 are well established^{5,6} while 3U1700-37 has an optical counterpart. All of these sources were observed more or less regularly at the same time as the new source thus enabling checks to be made on the self-consistency of the results. From these checks we conclude that there are as yet unresolved systematic variations within our positional determinations. The size of the error box shown surrounding our best fit position in Fig. 2 results chiefly from the systematic effects, the random errors being only of the order of $10''$.

It is clear from Fig. 2 that the source lies very close to the direction of the radio source Sgr A and the associated infrared emission region. We have also observed a number of other broadly similar transient X-ray sources^{7,8}. The probability of a chance alignment of such an event with this particular direction, although difficult to estimate in retrospect, is certainly low. Given that an event occurred within the field of view of the experiment during the observations of that region, the proba-

Fig. 2 The position and error box for the new source compared with a 5-GHz radio map of Sgr A west¹⁰.

bility of a chance alignment within $2'$ of Sgr A itself is $\lesssim 10^{-4}$. The probability that an event anywhere in the sky should be so aligned is of course lower than this. The probability of a similar alignment with any one of the 10 or so X-ray sources and other important features within this region is only an order of magnitude higher. It might be argued that the locally high stellar density close to Sgr A makes the occurrence of a transient similar to those observed in other regions very much higher. If the event occurred even close to Sgr A the distance must be ~ 10 kpc and this implies a peak flux of $5 \times 10^{38} \text{ erg s}^{-1}$ (3–10 kV), which is at the upper limit of the range of values usually encountered in galactic X-ray sources, perhaps suggesting again that this is a different type of phenomenon.

It is thus likely that the X-ray source is directly associated with one of the radio or infrared sources that lie within Sgr A. The fact that the rise and turnover of the light curve occurred on a time scale of the order of 2 d probably implies an emission region less than 0.002 pc in diameter. We note that long baseline interferometer studies have shown the presence of a source of less than $0.1''$ diameter (equivalent to 0.005 pc) in Sgr A west⁹, with a brightness temperature in excess of 10^9 – 10^7 K. A confirmation of this suggested association would require a change in radio or infrared emission from this region.

We thank J. C. Ives and K. A. Pounds for communicating their results before publication. We understand that a radio detection has been made by Jodrell Bank (personal communication).

Drifting subpulses and pulsar slowdown rates

MANY models^{1–3} have been proposed to explain the observed radiation from pulsars, but none has yet explained satisfactorily all the features of pulsar emission. Studies of the relationships between pulsar properties may help in the understanding of the nature and evolution of pulsars and we present here evidence for a close relationship between the direction of drifting of subpulses from a pulsar and its position in a P – \dot{P} diagram—the plot of the derivative of a pulsar's period, \dot{P} , against period, P .

In such a diagram (Fig. 1), derived from the data of Lyne, Ritchings and Smith⁴, pulsars in the top, left hand corner of the diagram are thought to be young. They evolve downwards and towards the right hand edge of the triangular distribution of points where the pulse emission mechanism breaks down and the pulsars 'die', for reasons predicted by the various models. Interestingly, those pulsars with complex pulse profiles or

Fig. 1 A plot of the period derivative, \dot{P} , against the period, P , for 84 pulsars⁴. +, Subpulses drifting later, —, drifting earlier; o, drifting in both directions. Numbers correspond to those given in Table 1.

drifting subpulses, which may be a sign of pulsar 'old age'⁵, lie close to that edge.

Single pulse observations of several pulsars have been made using the Mark 1A radio telescope at Jodrell Bank, and sequences of pulses showing subpulse drift have been recorded for the pulsars PSR1112+50, PSR1642–03, PSR1944+17 and PSR2319+60. The subpulses received from PSR2319+60 drift later, that is, they drift from the leading edge of the integrated pulse profile towards the trailing edge, whereas those from PSR1944+17 move in the opposite direction. PSR1112+50 and PSR1642–03 display sequences in which the subpulses drift in either direction. These 4 pulsars, together with 14 others whose subpulse drift has been discussed in the literature are listed in Table 1. Subpulse drift from PSR1237+25 has been reported by Backer^{6,13}, but in view of the comments of Taylor *et al.*⁷, it has not been included in Table 1. Each pulsar in Table 1 is also indicated in Fig. 1, and the direction of the subpulse drift is shown.

From Fig. 1 there seems to be a trend indicating that subpulses from pulsars of high \dot{P} drift later and that those from low \dot{P} pulsars drift earlier. The change in drift direction occurs at $\dot{P} \sim 0.2 \text{ ns d}^{-1}$. The pulsars showing drifting subpulses have been selected by observers principally on the basis of flux densities, since a good signal-to-noise ratio is required for the detection of any drift. It is not evident, however, how that or any other selection effect could give rise to the trend, although we cannot rule out completely the possibility that it is produced by the insufficient sampling of pulsars which have a random distribution of drift directions.

It is widely believed that subpulses are associated with

discrete sources of emission and that subpulse drift is caused by the sources moving asynchronously with the pulsar rotation rate, although it is not generally clear what determines their motion. The direction of motion of the sources of emission has been defined, however, only in the model of Ruderman and Sutherland³ and then the observed direction of drift will depend on the observer's line of sight relative to the pulsar magnetic pole and the rotation axis. It would be remarkable if a chance set of orientations has produced the effect shown in Fig. 1, and subsequent studies of the subpulse drift in more pulsars may exclude this possibility.

It seems that some form of dragging on the particle bunches

lead to a better understanding of the physics of pulsars.

+, Subpulses drifting later; —, subpulses drifting earlier; 0, subpulses which drift in both directions.

responsible for the subpulse radiation may be associated with the pulsar braking. This may not be significant for those pulsars with low values of \dot{P} (weak braking) and subpulses would drift earlier, but for high values of \dot{P} the dragging could be large and the particles may be 'forced' to move with different speeds, possibly in the opposite direction, thus producing the variation of subpulse drift direction with \dot{P} seen in Fig. 1. The exact nature of the association between the braking and dragging is not clear, but may be concerned with the magnetic dipole moment of the pulsar.

The dipole moment, M , is generally thought to be related to the rate of slowing down of the pulsar, according to $\dot{P} \propto M^2 P^{2-n}$, where n is the pulsar braking index which has experimental and theoretical values in the range 2.33–3 (see refs 1–4). In a plot such as Fig. 1, the evolutionary paths of pulsars would then be straight lines with slopes of between -0.33 and -1 and the wide range of \dot{P} would result from a spread in initial values of the dipole moment. If that is the case it would seem that subpulses drift later in pulsars with large dipole moments and in the opposite direction for pulsars with small dipole moments. It has been suggested that the evolution of pulsars involves a decrease in the effective dipole moment. That would happen if the pulsar magnetic field decayed¹⁴ or realigned¹⁵, or if its configuration in the magnetosphere became more complicated¹⁶ as the pulsar grew older. Then, the pulsar evolutionary lines would be straight initially but would later deviate to lower values of \dot{P} , eventually becoming almost vertical. Again, it seems that the subpulses drift later while the magnetic dipole moment is strong, but change their direction of drift when it becomes weaker in the later stages of the lifetime of the pulsar.

The relationship suggested here is based on the observation of a limited number of pulsars. Further observations are clearly required to test this apparent relationship, which may

Size of the Coma cluster

STUDIES of counts of galaxies in large regions centred on the Coma cluster led Zwicky to conclude that the radius of the Coma cluster is at least 6° (13 Mpc for $H = 55 \text{ km s}^{-1} \text{ Mpc}^{-1}$). Outside this radius, the contribution to the counts from fore-

Fig. 1 Line of sight velocity relative to the Local Group against radial distance from the centre of the Coma cluster. *a*, Coma cluster; *b*, Local Supercluster.

Fig. 2 Logarithm of the average number of galaxies in the Coma cluster with $m_p \leq 15.0$ mag per square degree against logarithm of the average radius of an annular ring. Error bars indicate the mean errors of sampling. The straight line has a slope of -1.18 .

ground and background galaxies overwhelms the contribution from the cluster, rendering it invisible. The technology of image intensifier tubes has now advanced to such an extent that it is feasible to obtain line of sight (radial) velocities of large numbers of galaxies in fields of a cluster. These velocities can be used to distinguish cluster members from foreground and background galaxies². Such studies have confirmed that the Coma cluster extends to at least 5° (ref. 3).

The reported study here, which completes work begun in 1972 (ref. 4), concentrates on a region $5-13^\circ$ west of the centre of the Coma cluster called cluster number 16 in field 158 by Zwicky and Herzog⁵. Spectrograms obtained with a Carnegie image tube on the 2.1-m telescope at the Kitt Peak National Observatory have been used to complete the determination of radial velocities for 50 of the 52 galaxies in cluster 16 with apparent magnitude $m_p \leq 15.0$ mag (a homogeneous sample). Some additional velocities of bright galaxies just outside the boundary of cluster 16 were also obtained. These data are used in conjunction with velocities for galaxies within 5° of the centre of the Coma cluster⁶⁻⁸ to plot radial velocity (relative to the Local Group), V_0 , against distance from the centre of the Coma cluster, r (Fig. 1).

Cluster 16 is clearly resolved into three components: (1) part of the Local Supercluster (V_0 between 200 and 1,300 km s⁻¹), (2) groups with V_0 between 2,200 and 4,200 km s⁻¹, and (3) the Coma cluster with velocities in the range 6,300–9,100 km s⁻¹. Galaxies in the Coma cluster with radial distance up to 14.2° are recognised, so the Coma cluster has been detected to $r = 32$ Mpc.

Seventeen galaxies (34%) of our homogeneous sample are cluster members. Fourteen of these can be categorised into morphological types⁹, and 7–8 (50–57%) are spirals. This fraction is consistent with the tendency for the relative number of spirals to increase with radial distance found for the inner 2.79° of the cluster⁶.

The data of our homogeneous sample have been combined with other homogeneous data⁶⁻⁸ to derive the average surface density (galaxies with $m_p \geq 15.0$ mag per square degree) against distance from the centre of the Coma cluster for the r interval $1.67-12.4^\circ$ (Fig. 2). A χ^2 fit of the data to a power law reveals that the surface density is proportional to $r^{-1.18 \pm 0.24}$, which

is consistent with the formula for an isothermal sphere found to apply in the inner regions of the cluster^{1,10-12}. If the empirical formula for surface density applies to even greater radial distances, then we expect 12% of a sample of galaxies with $m_p \leq 15.0$ mag at $r = 20^\circ$ (and 4.5% at 45°) to be members of the Coma cluster.

Our homogeneous sample, which is centred at $r = 8.5^\circ$, has a mean radial velocity of 7,639 km s⁻¹ and a standard deviation about this average of 751 km s⁻¹. The inner region, of the Coma cluster, radius 2.79° , has a mean radial velocity of 6,981 km s⁻¹ and a standard deviation of 920 km s⁻¹. The greater mean velocity of our homogeneous sample (by 2.4σ) relative to the inner region of the cluster may be a statistical fluctuation. If cluster members just outside the region of the homogeneous sample are included, then the average velocity reduces to 7,374 km s⁻¹.

An outer radius for the Coma cluster of at least 32 Mpc makes it one of the largest known cosmic entities. Its size is at least as great as the size of the Local Supercluster and typical groups of galaxy clusters (H.J.R., unpublished). A galaxy moving with a velocity of $900\sqrt{3}$ km s⁻¹ would take 2×10^{10} years to travel 32 Mpc. Thus gravitational mixing of galaxies between the inner and outer regions of the Coma cluster is not well advanced, and the properties of the outer regions reflect to a significant extent the initial conditions of the cluster formation period following the origin of the Universe.

The density of rich clusters of galaxies is of the order of 0.8×10^{-6} clusters Mpc⁻³. If the Coma cluster is a fairly typical cluster, as it seems to be^{13,14}, the new findings require a mass of $M(\text{Coma}) \geq 1.3 \times 10^{16} M_\odot$ and a density of the Universe $\geq 7.1 \times 10^{-31}$ g cm⁻³ = $0.12(3H_0^2/8\pi G) = 0.12\rho_c$.

Possible origin of lunar magnetism

ANY model of the origin of lunar magnetism needs to explain two principal observations¹. One is the magnitude of the stable natural remanent magnetisation (NRM) carried by the returned lunar samples, which is far too large to have been acquired in fields comparable with those found at present in the vicinity of the Moon. The other is the presence of remanent fields at the lunar surface, which imply source regions of tens or hundreds of kilometres of homogeneous magnetisation, primarily in the highlands.

Attempts to explain these phenomena include the suggestion that the Moon had, early in its history, a regenerative dynamo like the Earth's, so that the magnetisation now observed was acquired in its field². It has also been proposed that the Moon
